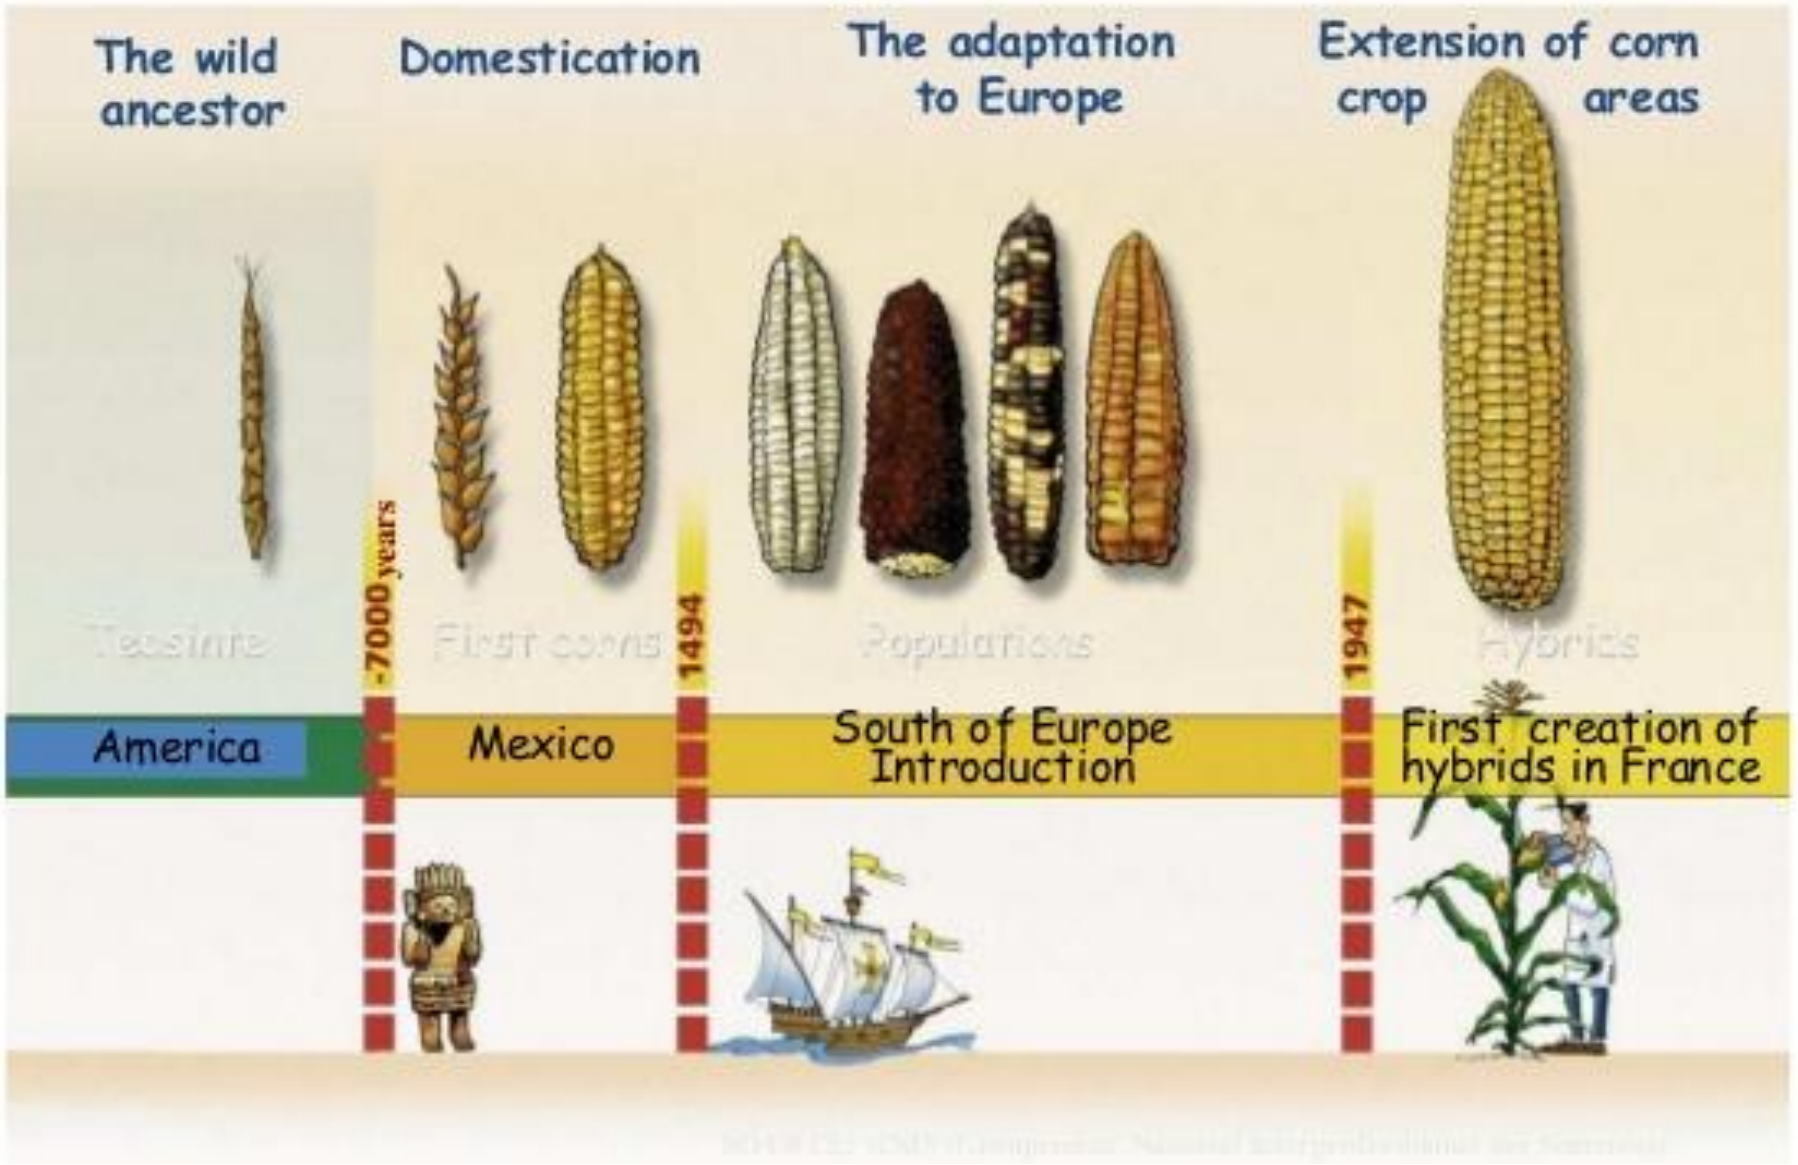
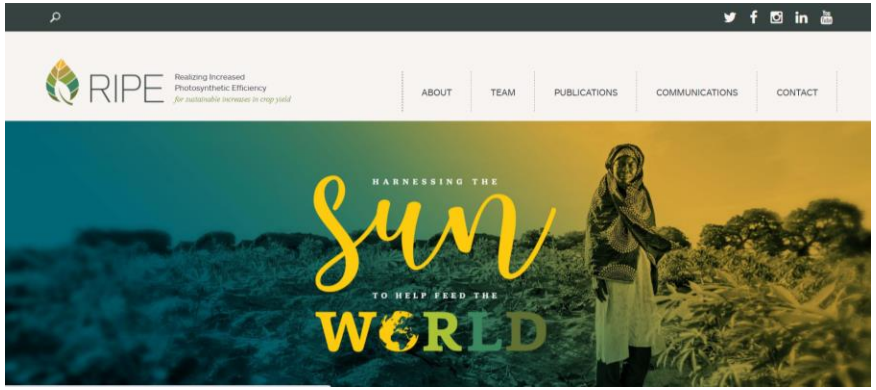
Is it possible to improve primary metabolism efficiency?

Is there still room for the improvement of crop yield?



https://ripe.illinois.edu/



Objectives

Our strategy is to probe a mathematical representation of the whole photosynthetic process in silico to identify which of billions of possible changes might be the most rewarding in practice to boost the yields of key food crops. Top candidates are then tested in a single cultivate of tobacco; why tobacco? Tobacco was selected for our proof-of-concept experiments, not only for its ease of genetic transformation, but also because it is an ideal model crop that is robust in the field, forms a fully closed canopy, and produces large quantities of seed, circumventing the need for numerous seed amplification generations, further accelerating the timeline to field testing. When statistical evidence of productivity increase is achieved in tobacco, then the successful manipulations are transferred to the food crops of interest: cowpea, rice, cassava, and soybean.

Identify

We simulate photosynthesis in silico from gene to canopy to discover opportunities that could improve photosynthesis and boost yield.

https://ripe.illinois.edu/

Improve

Next we explore each opportunity to increase photosynthetic efficiency by engineering a model crop, which enables us to make modifications with precision and speed.

- Relaxing Photoprotection
- Photorespiratory Bypass
- RuBP Regeneration
- Improving Rubiscos
- Optimizing Canopies
- Algal Mechanisms
- Mesophyll Conductance

Translate

Finally, we transform our target food crops with the successful modifications to boost the yield of cowpea, cassava, rice, and soybeans.

A feeling for the numbers in biology

Rob Phillips[a] and Ron Milo[b,1]

[a]*Departments of Applied Physics and Bioengineering, California Institute of Technology, Pasadena, CA 91125; and* [b]*Department of Plant Sciences, Weizmann Institute of Science, Rehovot 76100, Israel*

Edited by Ken A. Dill, University of California, San Francisco, CA, and approved October 30, 2009 (received for review July 14, 2009)

Although the quantitative description of biological systems has been going on for centuries, recent advances in the measurement of phenomena ranging from metabolism to gene expression to signal transduction have resulted in a new emphasis on biological numeracy. This article describes the confluence of two different approaches to biological numbers. First, an impressive array of quantitative measurements make it possible to develop intuition about biological numbers ranging from how many gigatons of atmospheric carbon are fixed every year in the process of photosynthesis to the number of membrane transporters needed to provide sugars to rapidly dividing *Escherichia coli* cells. As a result of the vast array of such quantitative data, the BioNumbers web site has recently been developed as a repository for biology by the numbers. Second, a complementary and powerful tradition of numerical estimates familiar from the physical sciences and canonized in the so-called ''Fermi problems'' calls for efforts to estimate key biological quantities on the basis of a few foundational facts and simple ideas from physics and chemistry. In this article, we describe these two approaches and illustrate their synergism in several particularly appealing case studies. These case studies reveal the impact that an emphasis on numbers can have on important biological questions.

bionumbers | order of magnitude | physical biology

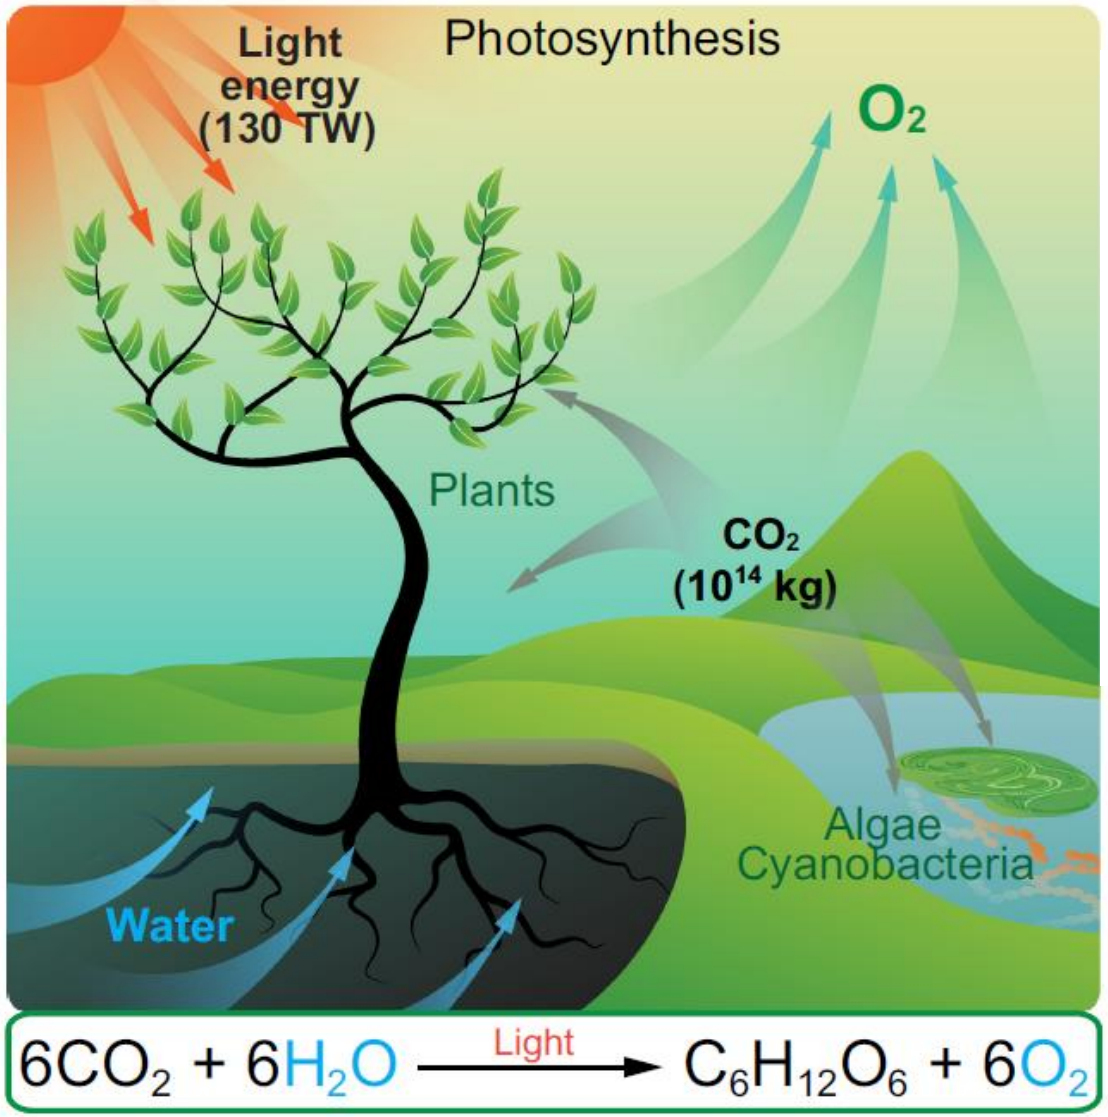
PERSPECTIVE

- More than 90% of the inorganic carbon that is converted into biomass is fixed by the enzyme RubisCO.
- RubisCO catalyzes the carboxylation and cleavage of ribulose-1,5-bisphosphate (RuBP) into two molecules of 3-phospho- glycerate (3PG).
- RubisCO is found in all three domains of life: bacteria, archaea and eukaryotes.
- The enzyme makes up 30–50% of the soluble protein in plant leaf
- For every person on earth there is 5 kg of RubisCO. Altogether, this makes RubisCO one of the most abundant enzymes in the global carbon cycle that literally feeds life on earth.

Review

Chaperone Machineries of Rubisco – The Most Abundant Enzyme

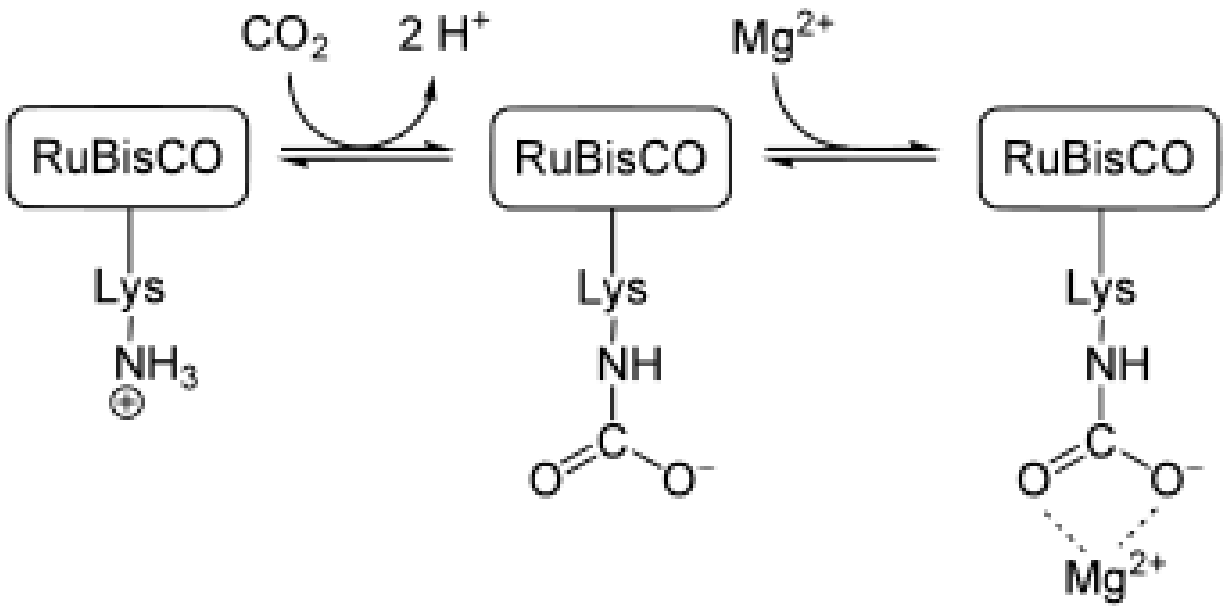
Manajit Hayer-Hartl [1,*] and F. Ulrich Hartl [1,*]

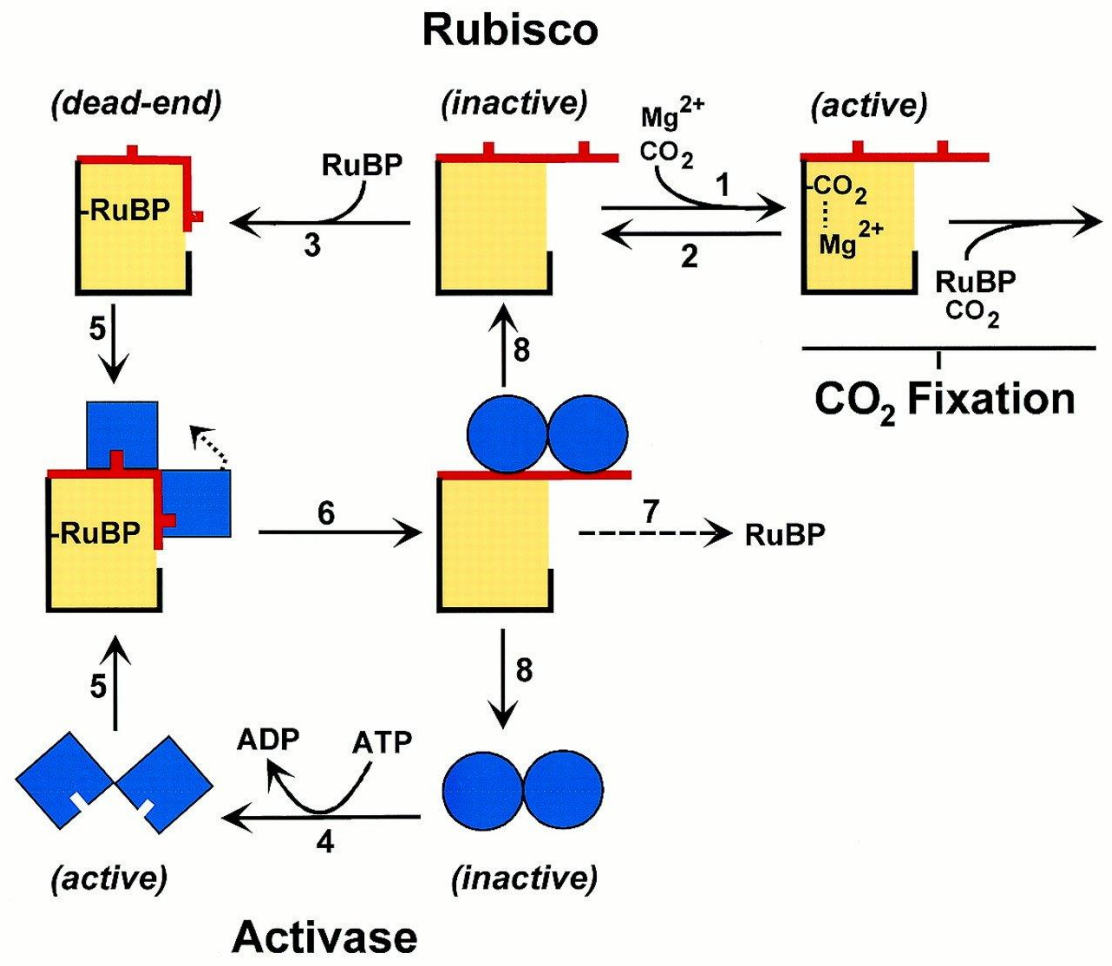


all food sources for life on Earth and maintains the oxygen level of the atmosphere. The human population currently stands at ~7.8 billion, and is expected to grow to ~10 billion by 2050 [1]. However, not only is the current overall **agricultural productivity** (see Glossary) not keeping pace with population growth, it is actually expected to decline in the course of this century due to climate change, especially in the southern regions of the planet [2]. For example, by 2030 Southern Africa could lose more than 30% of maize production, its main crop, and South Asia could suffer losses of more than 10% for many regional staples, such as rice, millet, and maize [3]. Climate change affects agriculture in various ways, including through changes in average and local temperatures, regional climate extremes, and droughts. In the face of these challenges, it seems unlikely that future **food security** can be ensured without increasing photosynthetic carbon fixation by genetically engineering crop plants [4–9]. Making photosynthesis more efficient would not only increase productivity but also enhance agricultural sustainability by optimizing the use of resources and minimizing the impact on the environment [10].

RubisCO peculiarities

1. A **conserved lysine** residue in the active site needs to be carbamylated in order to complex an Mg2+ ion that is in turn required for activity.

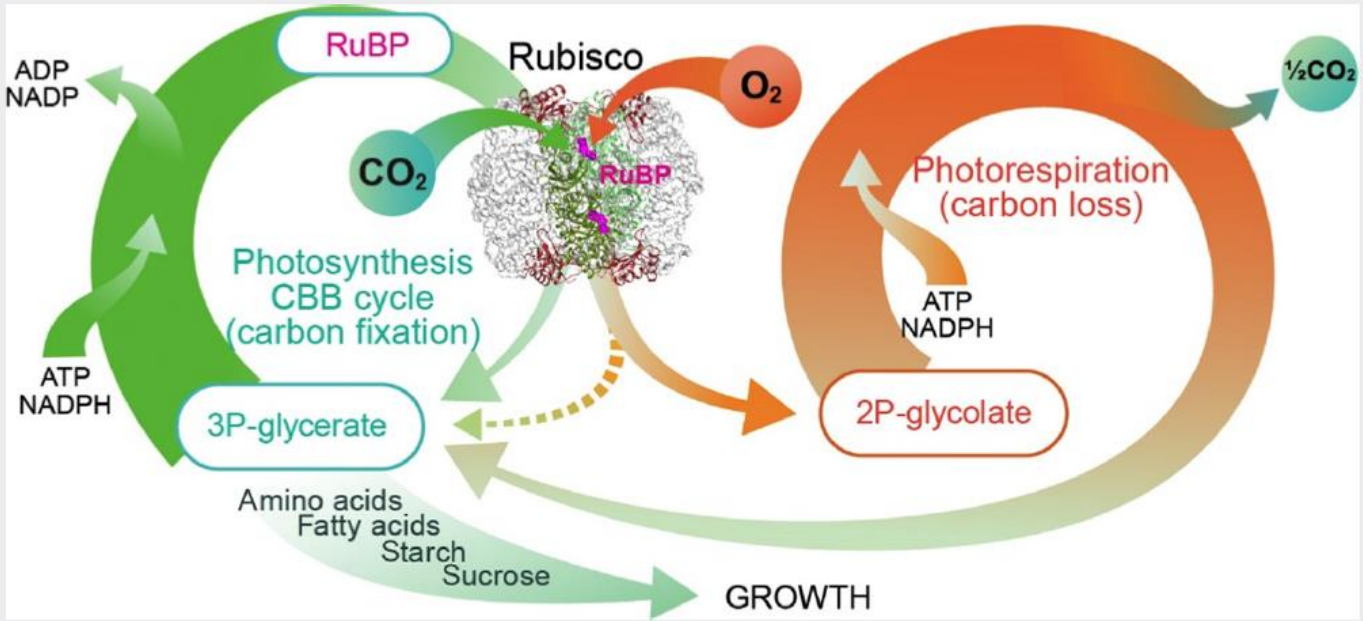




https://www.pnas.org/doi/10.1073/pnas.97.24.12937

RubisCO peculiarities

1. A conserved lysine residue in the active site needs to be carbamylated in order to complex an Mg2+ ion that is in turn required for activity.
2. the enzyme is a rather slow catalyst. The turnover frequency of an average RubisCO is only between 1 and 10 s^{-1} (http:// brenda-enzymes.org), which can make it a limiting factor in photosynthetic CO2-fixation under optimal conditions.
3. RubisCO makes mistakes. Besides the carboxylation reaction RubisCO catalyzes a non-productive oxygenation side-reaction that leads to the formation of 2- phosphoglycolate (2PG).



(B)

Amount of CO_2 fixed globally per annum:	~10^{14} kg
Total mass of Rubisco:	~7 x 10^{11} kg (~96 % terrestrial, ~4 % marine)
Time-averaged catalytic rate:	~0.03 s^{-1} terrestrial Rubisco ~0.6 s^{-1} marine Rubisco
CO_2 molecules fixed per second:	~2 x 10^{32} terrestrial Rubisco ~1.5 x 10^{32} marine Rubisco

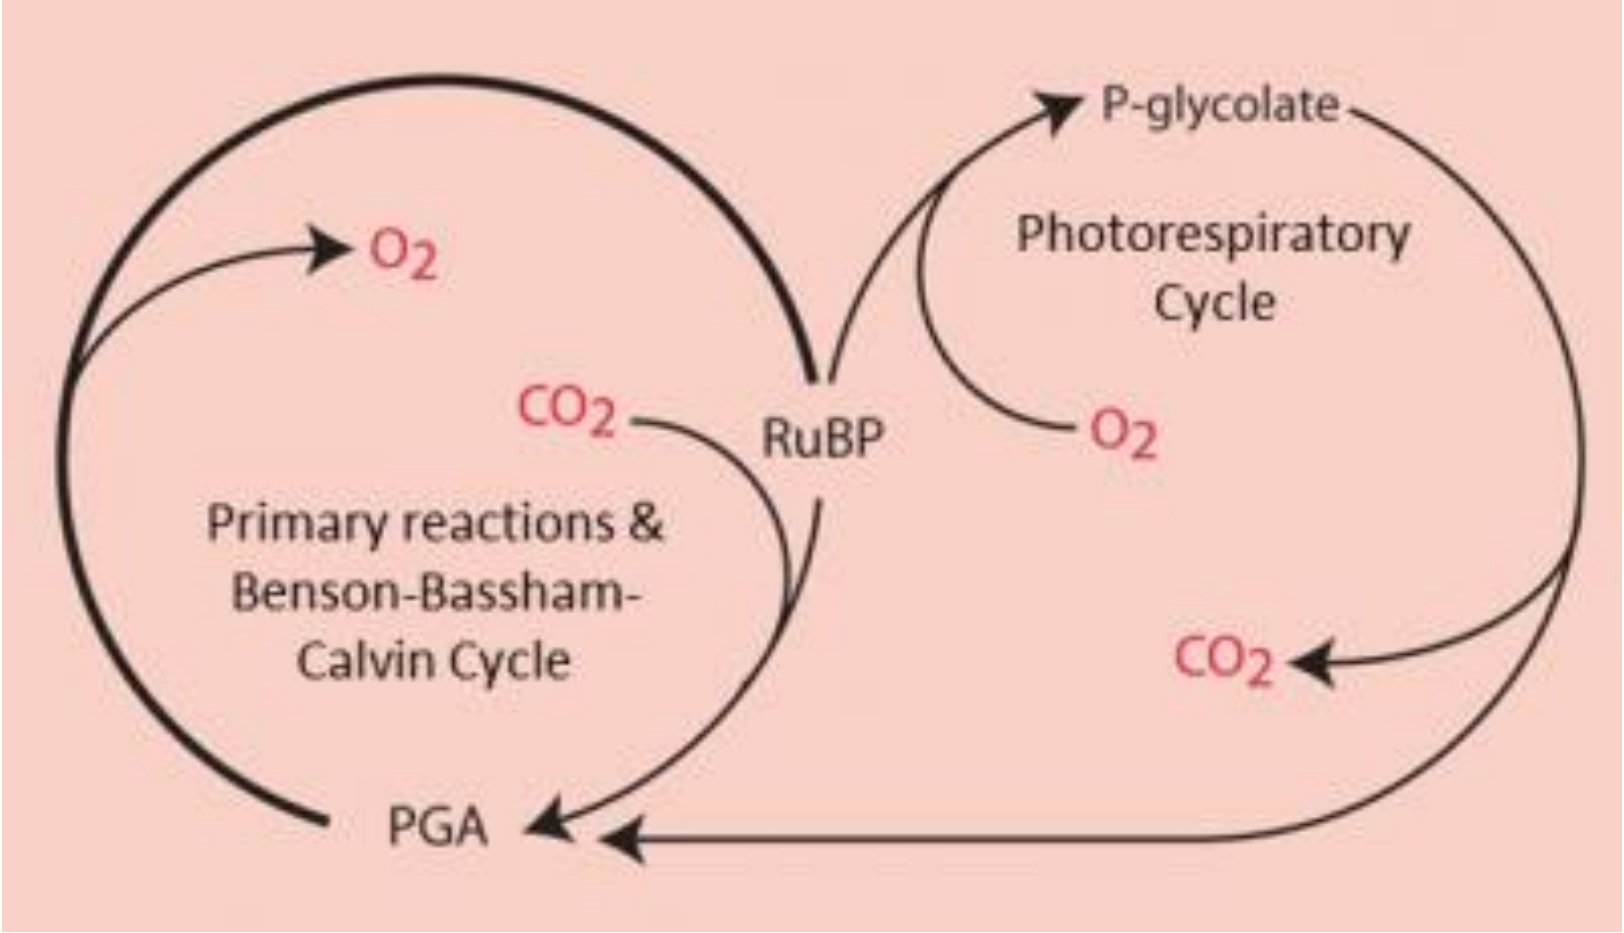
Trends in Biochemical Sciences

An important limitation in photosynthesis is the poor performance of Rubisco due to its dual carboxylase and oxygenase activity.

At ambient CO_2 levels, the carboxylase and oxygenase activities compete with each other, leading to a significant decrease in carbon fixation through photorespiration.

Photorespiration creates a product (2-Pglycolate) that cannot be used to make sugars and hence reduces the efficiency of the Calvin cycle

Photorespiration reduces levels of photosynthesis by up to ~25% in C3 plants, reducing energy yield in these plants



https://www.encyclopedie-environnement.org/en/life/path-carbon-photosynthesis/

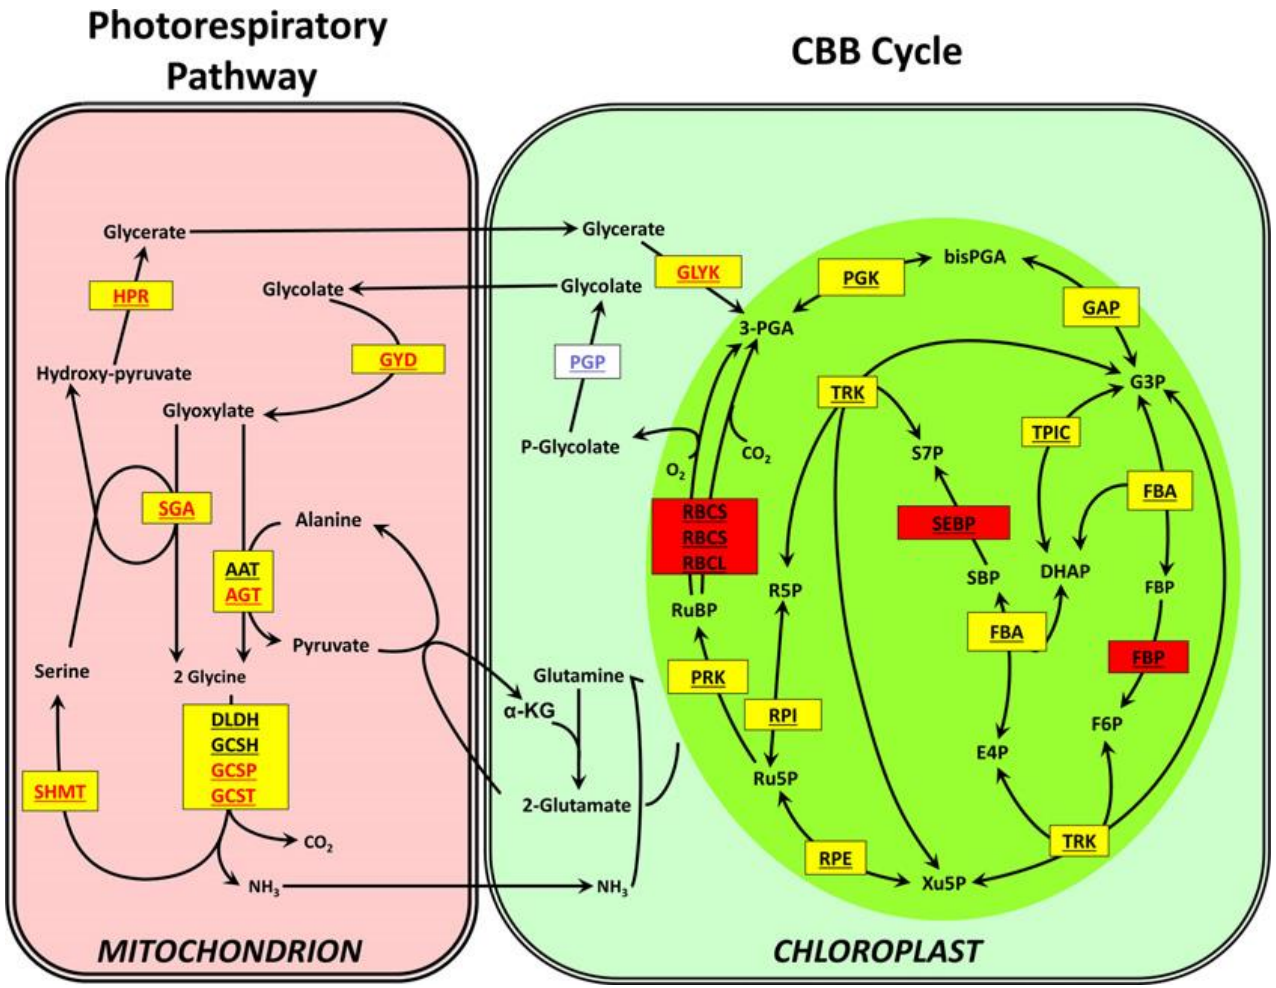
SI CHLAMYDOMONAS

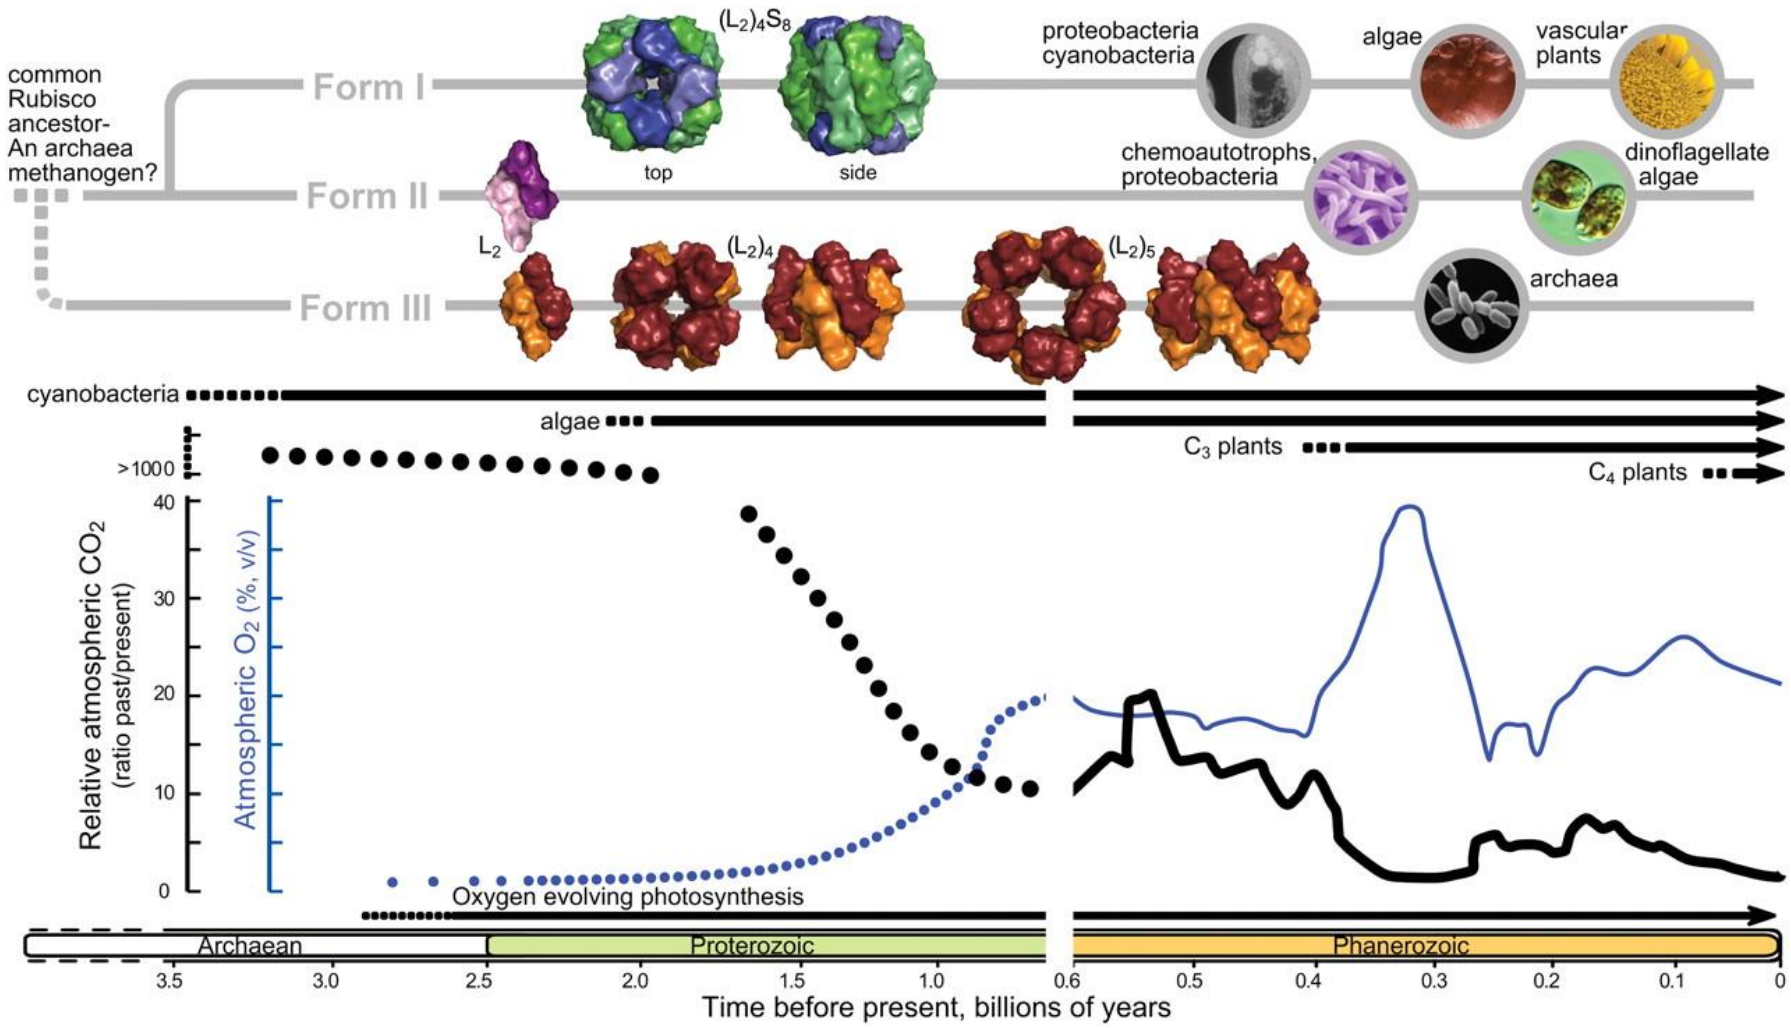
The CO_2 concentrating mechanism and photosynthetic carbon assimilation in limiting CO_2: how Chlamydomonas works against the gradient

Yingjun Wang, Dan J. Stessman and Martin H. Spalding*
Department of Genetics, Development, and Cell Biology, Iowa State University, Ames, Iowa, USA



Chlamydomonas oxidizes glycolate to glyoxylate utilizing a glycolate dehydrogenase located in the mitochondria, donating electrons to the ubiquinone pool of the respiratory electron transport chain.

Over the past **three billion years**, the carbon-fixing enzyme **Rubisco drew down atmospheric concentrations of CO_2** to trace levels, in effect **starving itself** of its substrate.



Why is RubisCO so inefficient?

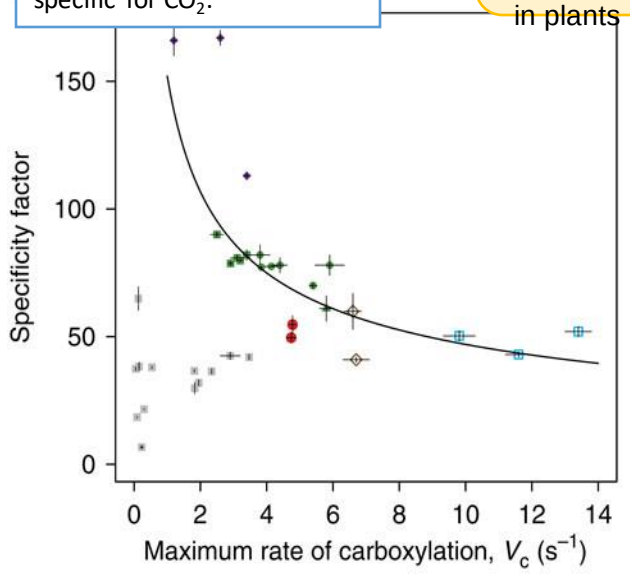
- Evidence accumulated that enzyme activity and specificity are reciprocally linked with each other in RubisCO.
- A faster RubisCO has a higher error rate and a more specific RubisCO has a lower catalytic rate.
- RubisCO evolved before the first great oxygenation event in an atmosphere without oxygen (O2), so that its mechanism was not constrained by O2.
- However, with the rise of atmospheric O2 concentrations to modern-day levels, as a result of the second great oxygenation event, RubisCO had to learn to discriminate between CO2 and O2. Because discrimination usually comes at the cost of reduced catalytic rate, a more specific enzymes almost inevitably becomes a slower catalyst

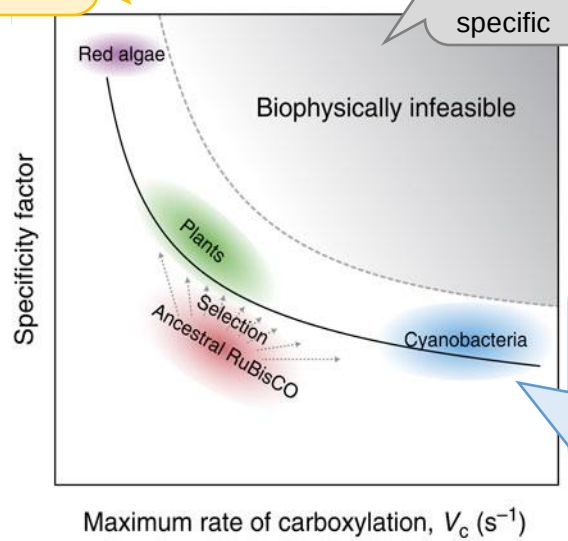
Different forms of Rubisco in nature

Specificity factor indicates the specificity of the enzyme for CO_2 relative to O_2. Higher means more specific for CO_2.

Rubisco in red algae is more specific but slower than that in plants

In many organisms, the enzyme cannot be both fast and specific

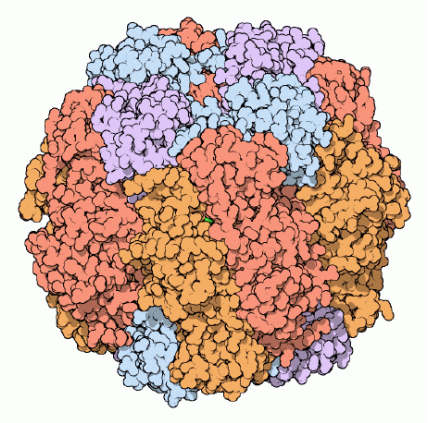




Rubisco in cyanobacteria algae is faster but less specific than that in plants

Shih P.M., Occhialini A., Cameron J.C., Andralojc P.J., Parry M.A.J.and Kerfeld C.A. (2016). Biochemical characterization of predicted Precambrian RuBisCO. Nat Commun 7: 10382.
See also Whitney, S.M., Houtz, R.L. and Alonso, H. (2011). Advancing our understanding and capacity to engineer Nature's CO_2-sequestering enzyme, Rubisco. Plant Physiol. 155: 27-35.

How algae and cyanobacteria solved this problem?

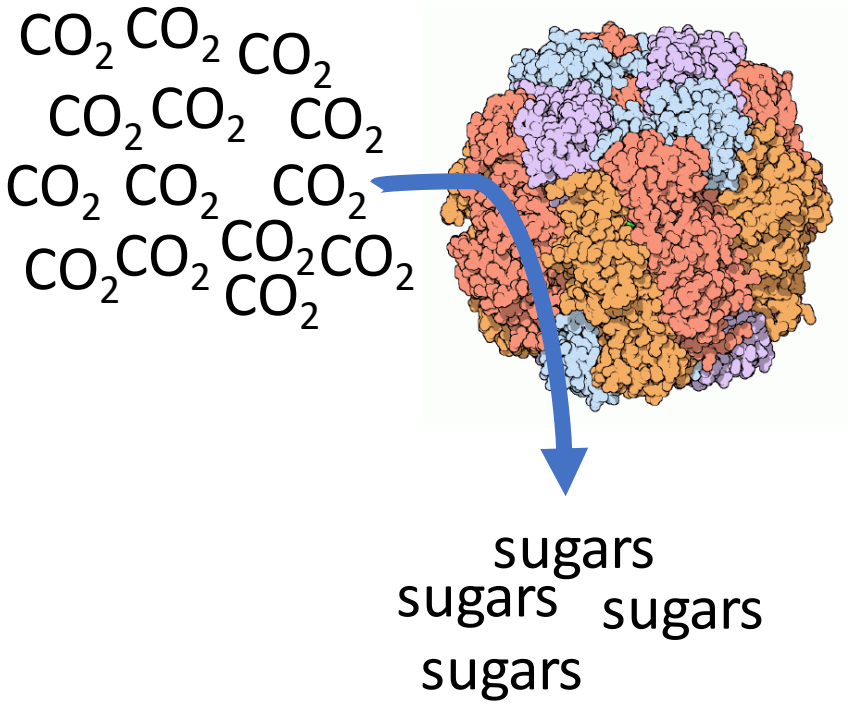


Amount of CO_2 fixed globally per annum:	~10^{14} kg
Total mass of Rubisco:	~7 x 10^{11} kg (~96 % terrestrial, ~4 % marine)
Time-averaged catalytic rate:	~0.03 s^{-1} terrestrial Rubisco ~0.6 s^{-1} marine Rubisco
CO_2 molecules fixed per second:	~2 x 10^{32} terrestrial Rubisco ~1.5 x 10^{32} marine Rubisco

Trends in Biochemical Sciences

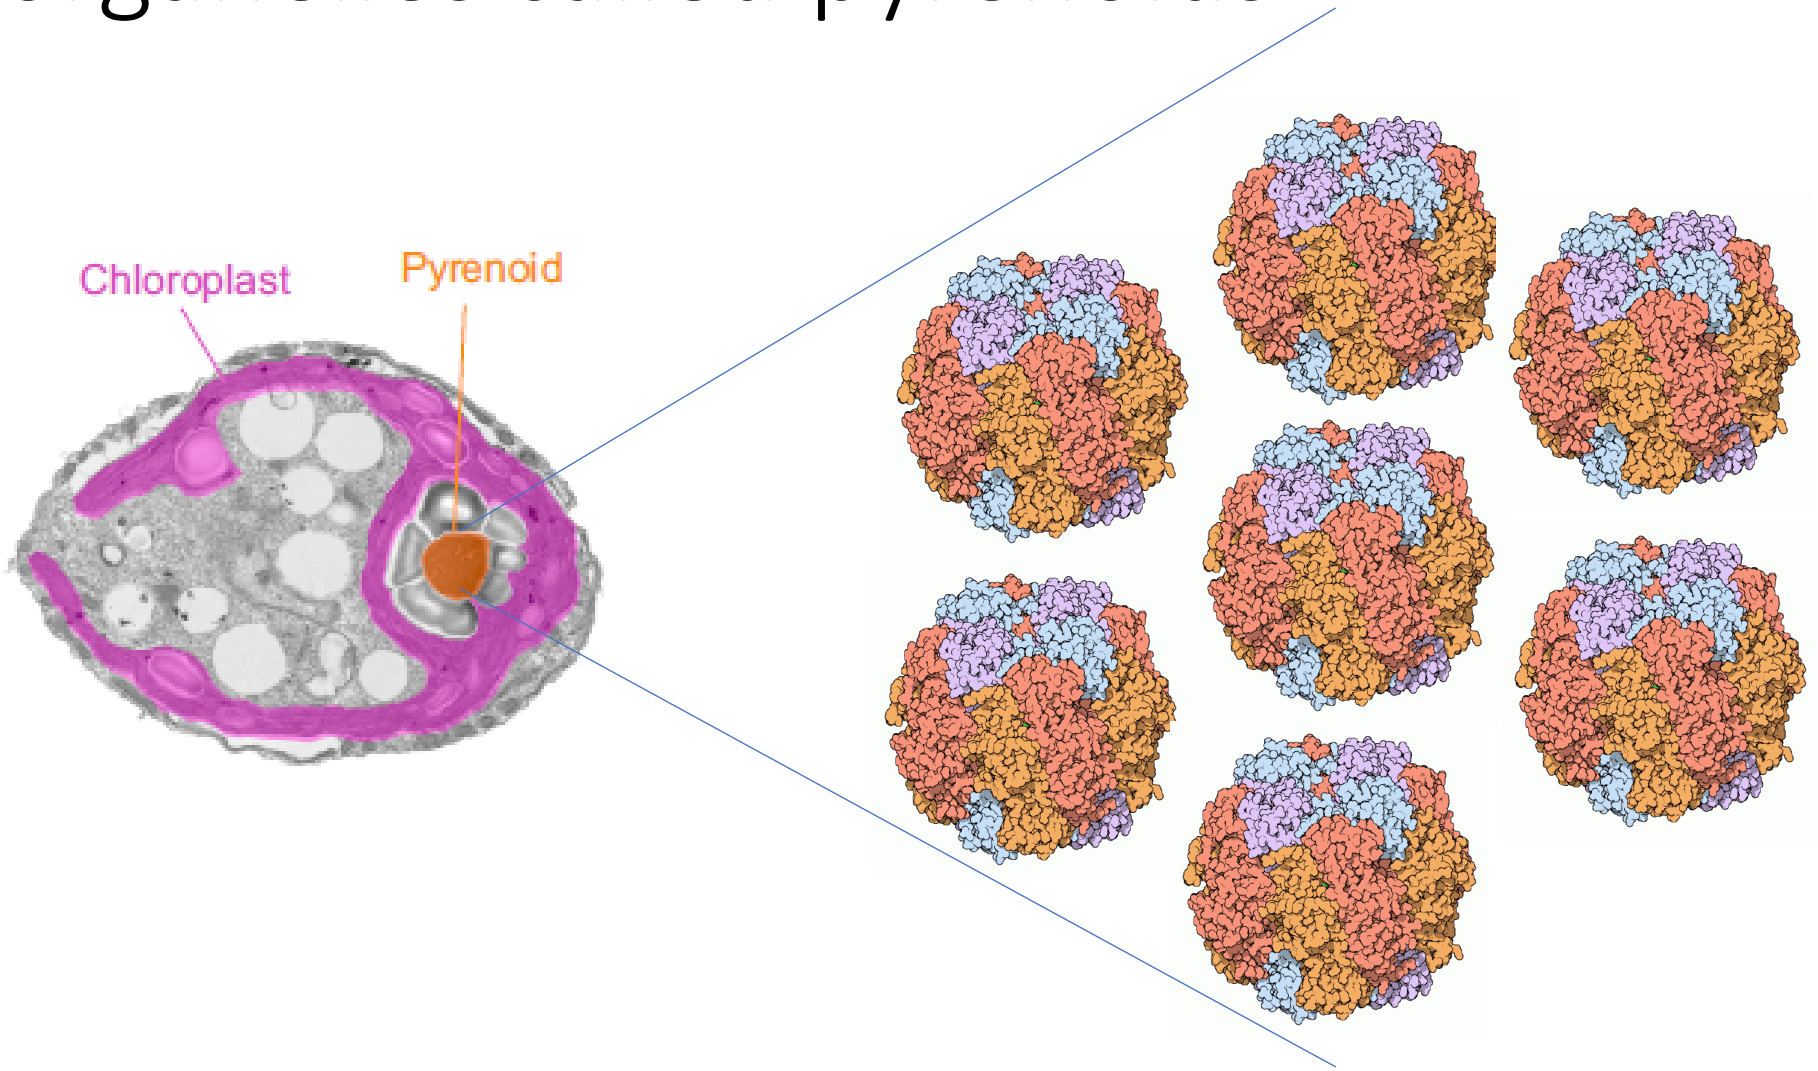
How algae and cyanobacteria solved this problem?

by increasing the level of CO_2 in the vicinity of Rubisco through CO_2-concentrating mechanisms (CCM)



Microalgae and pyrenoids

By packing RUBISCO in specialized organelles called pyrenoids



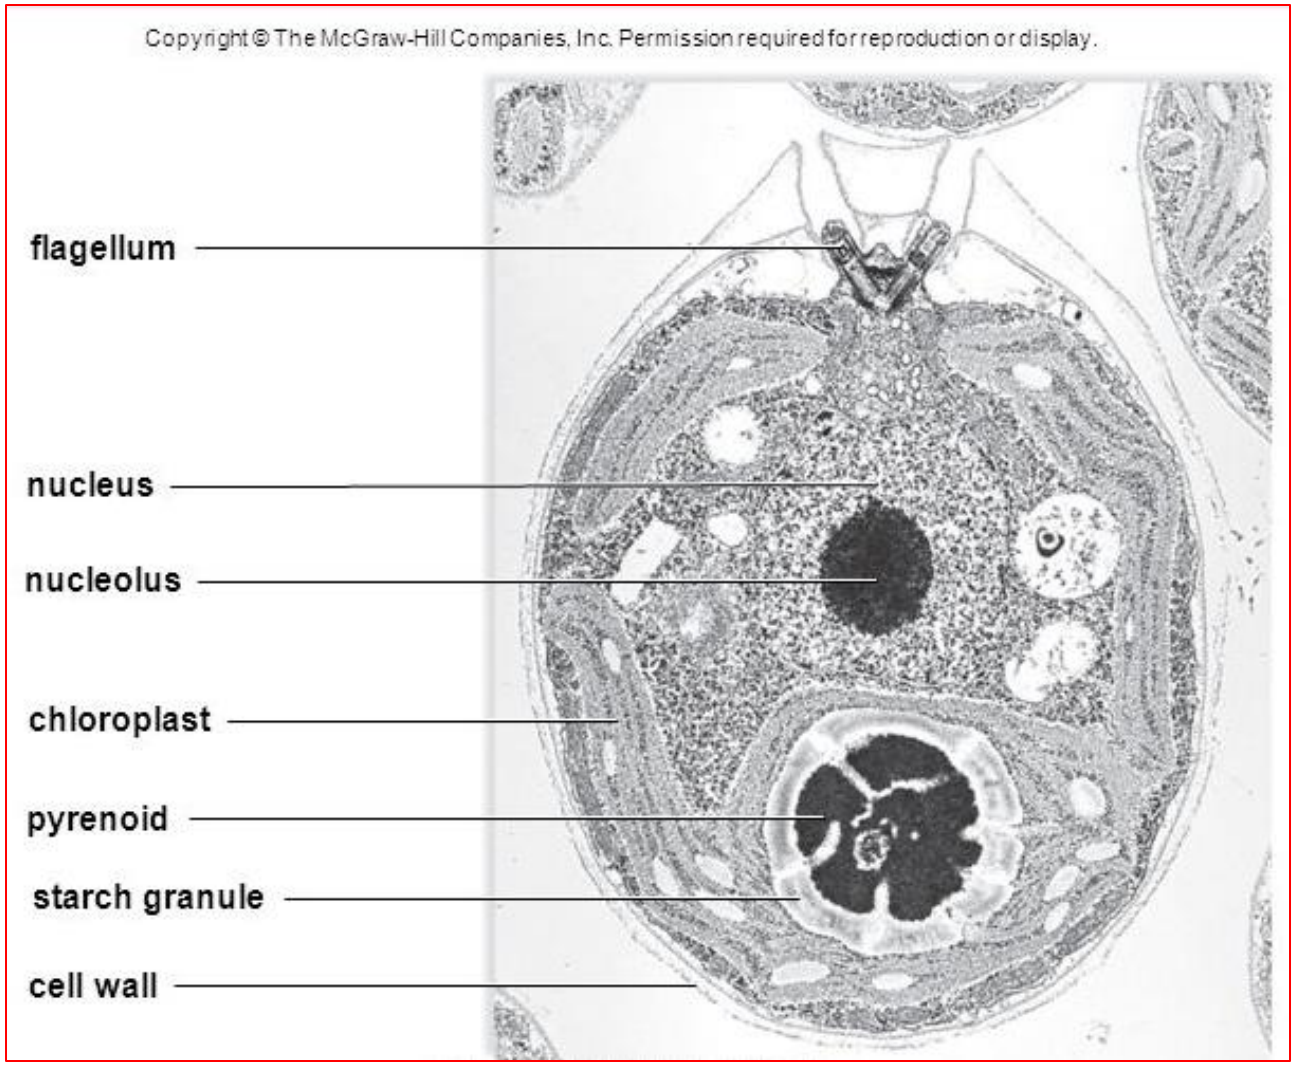
Proposed synthetic biology approach:

Introducing non-plant Carbon Concentrating Mechanisms (CCMs) into C3 plant

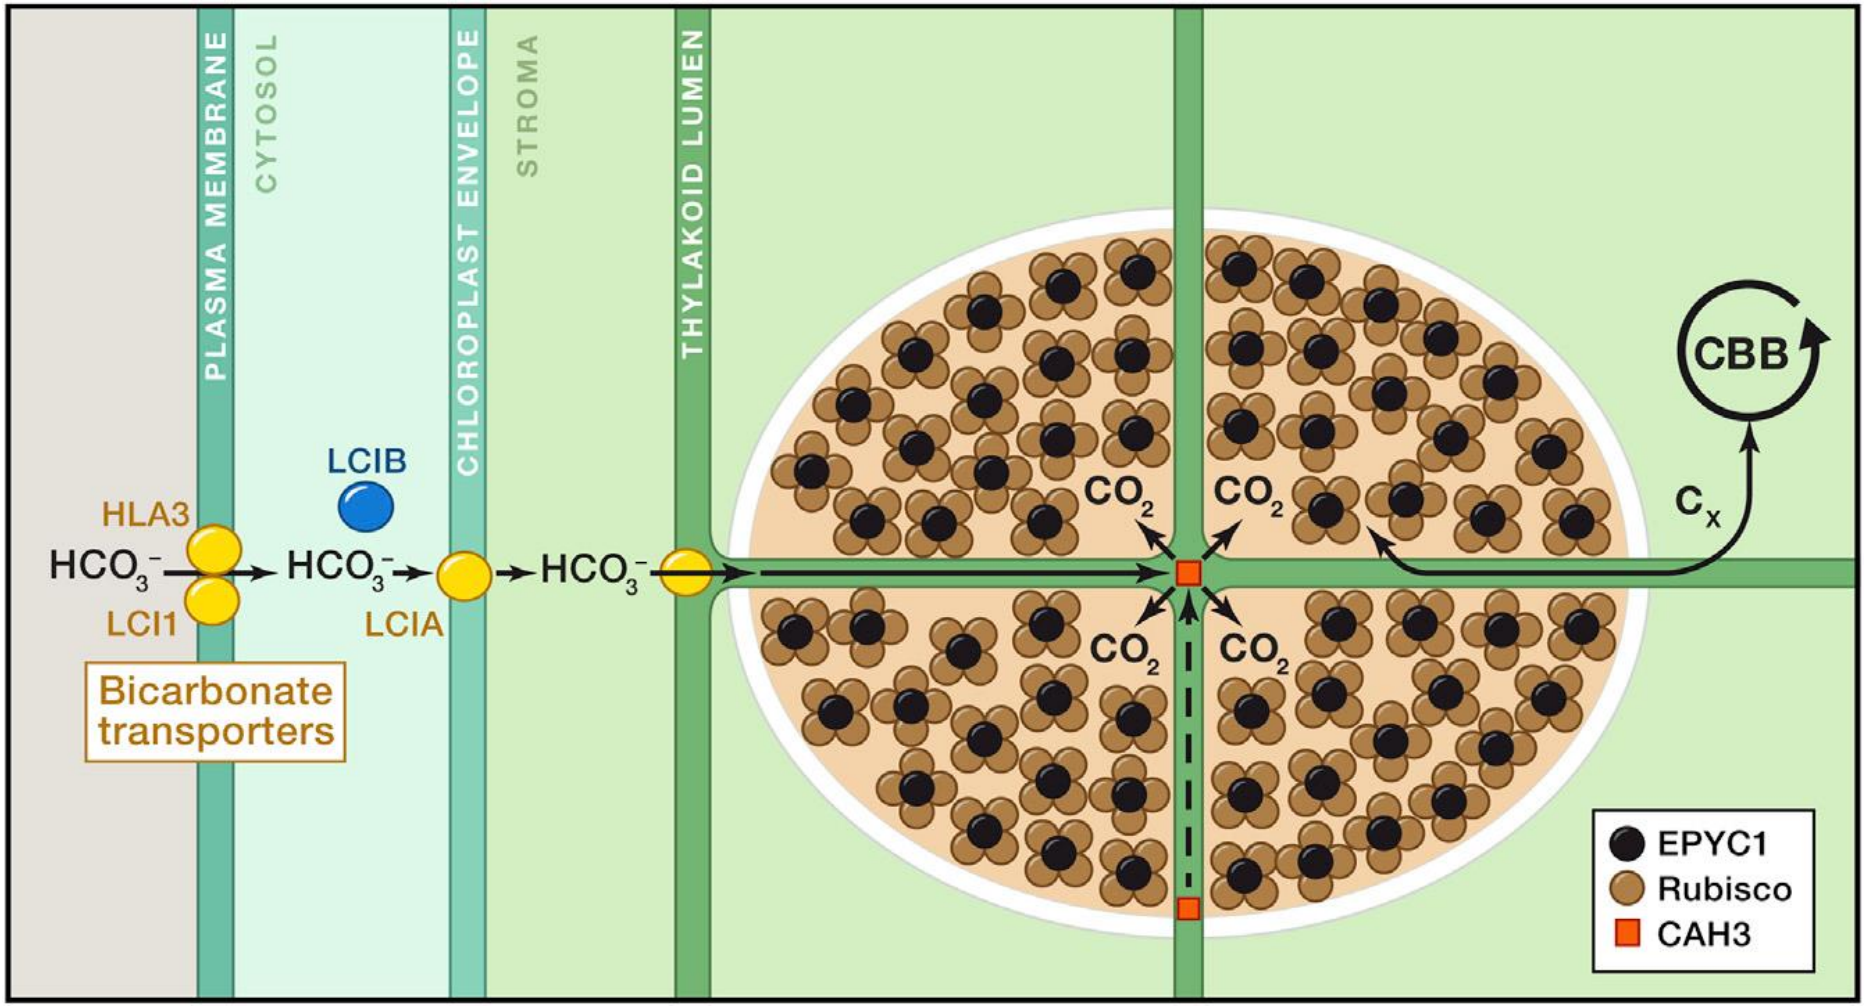
One approach to improving plant photosynthesis is using engineering to implement CCMs from other photosynthetic organisms such as cyanobacteria or algae.

Pyrenoid, a membraneless organelle within chloroplasts, where approximately **one-third of global CO_2 fixation is estimated to occur**

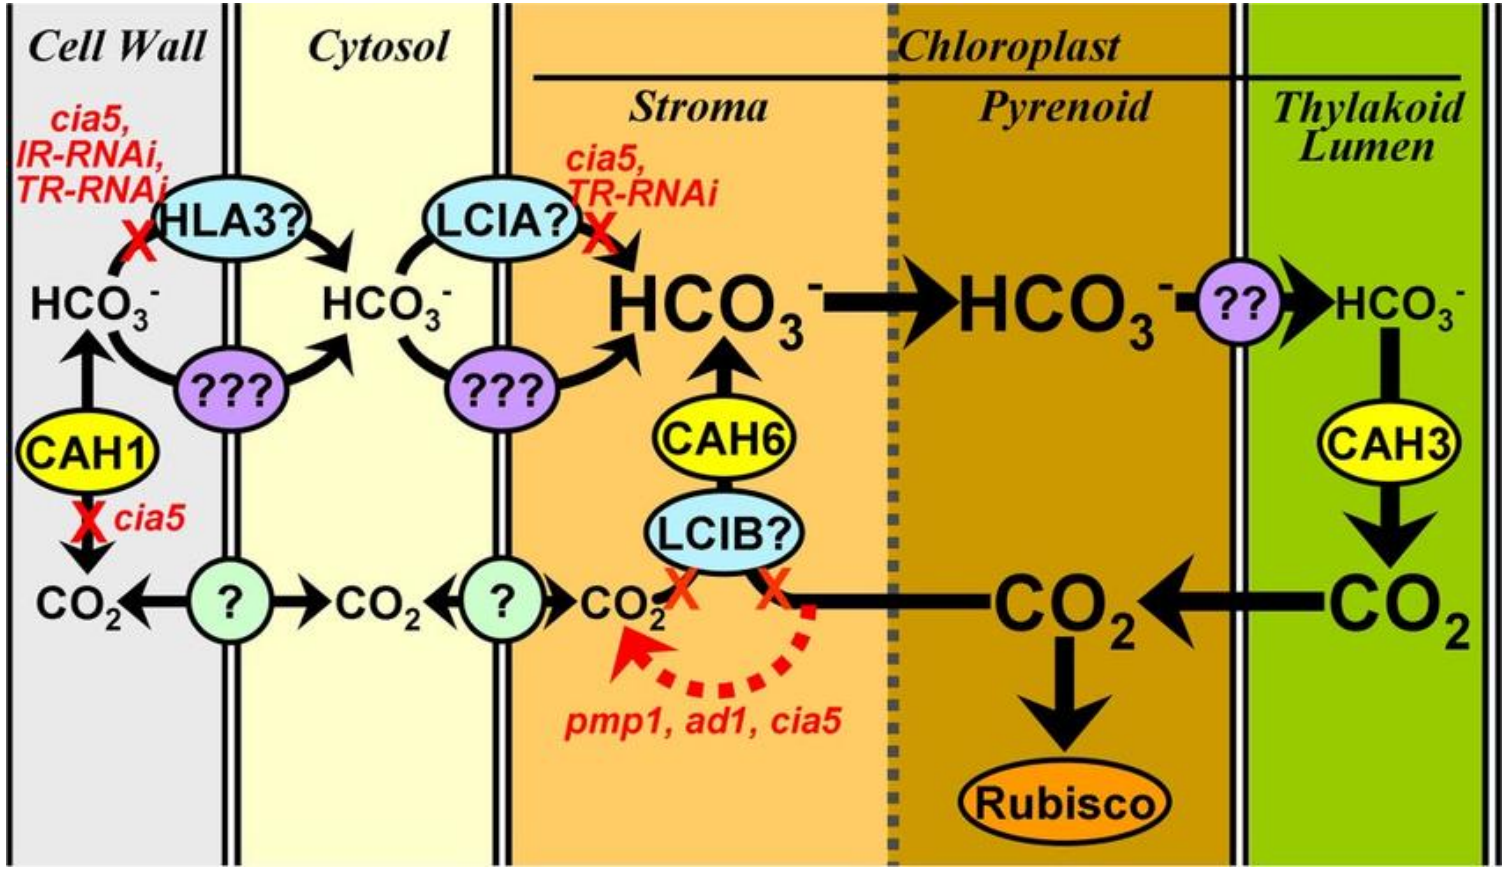
The pyrenoid contains a starch sheath and a matrix in which CO_2 is concentrated together with Rubisco. The matrix is traversed by membrane tubules that are continuous with the thylakoid membranes.



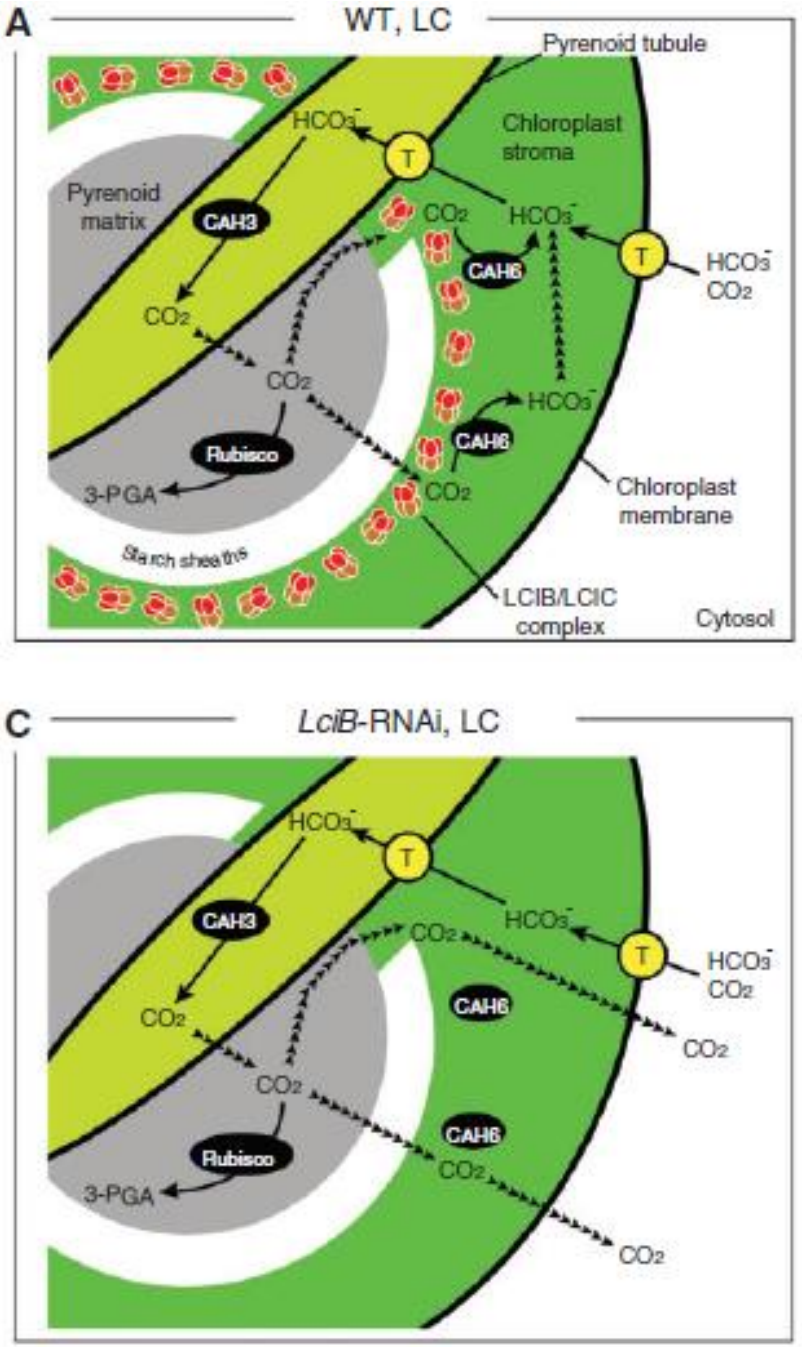
In algae, CCM is mediated by several plasma and chloroplast-membrane inorganic carbon transporters, a set of carbonic anhydrases in strategic locations



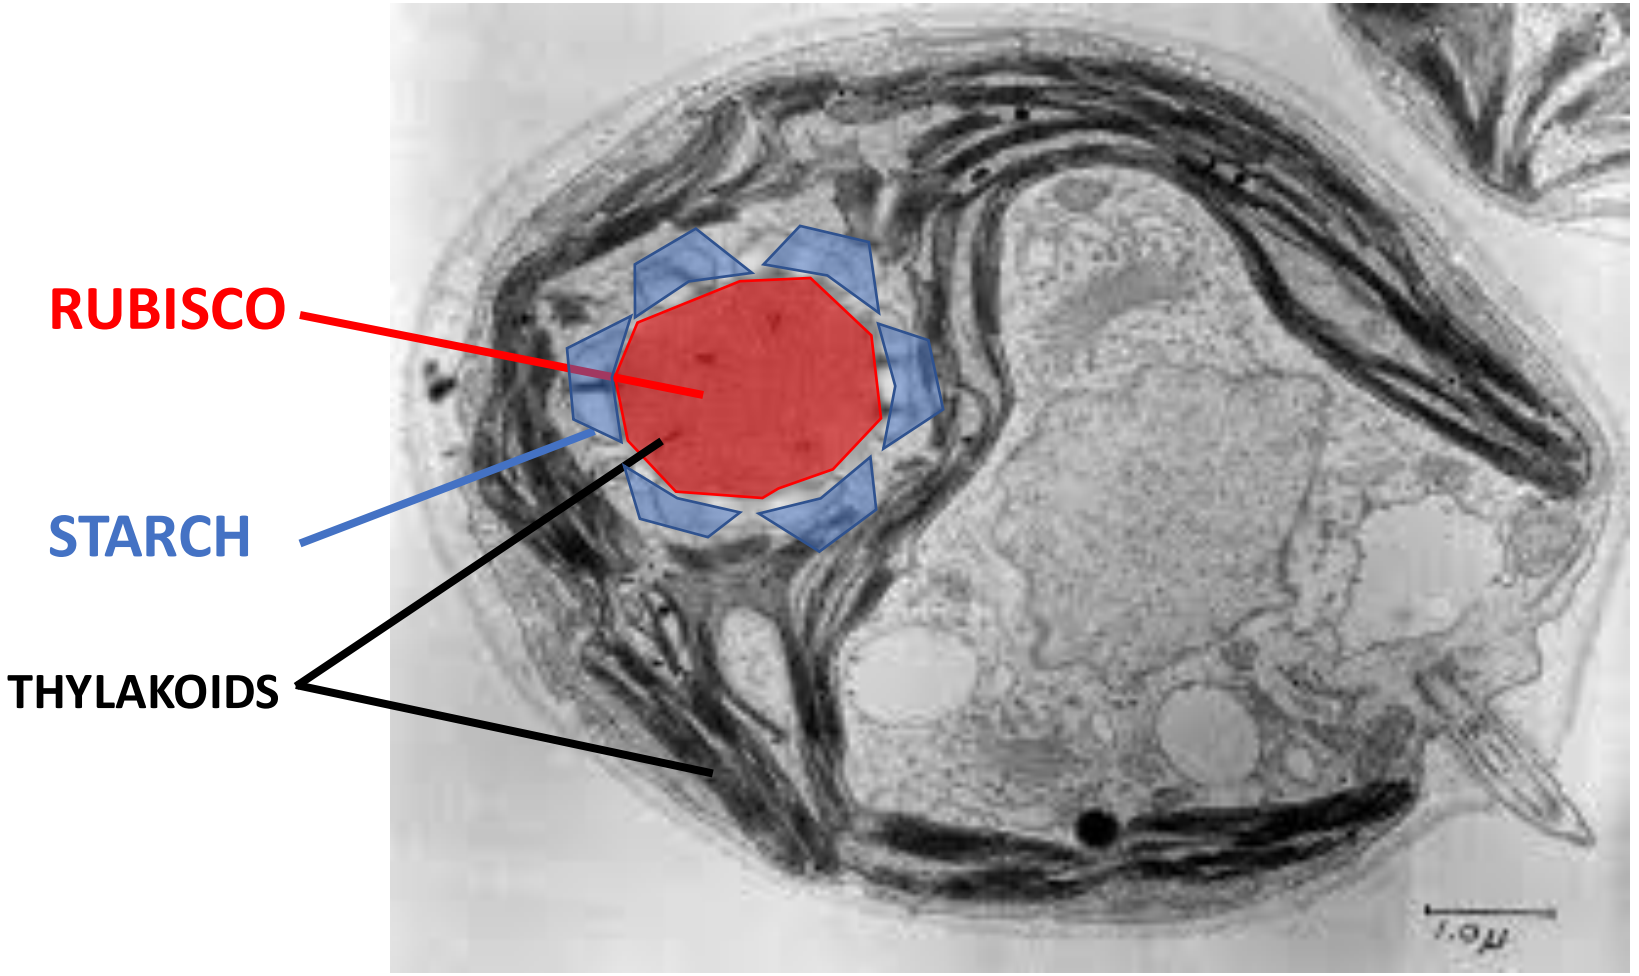
Ci, including the charged species, bicarbonate (HCO_3^-), must cross both the plasma membrane and the chloroplast envelope to reach Rubisco, yet the roles, if any, of proposed and confirmed Ci transporters, including the plasma membrane proteins HLA3 and LimitingCO_2 Inducible1 (LCI1) and the chloroplast envelope proteins LCIA (NAR1.2), CCP1, and CCP2



Many mutants affected in CCM have been identified based on their ability to grow photoautotrophically under high-CO_2 but not under low-CO_2 conditions.



Many mysteries surround pyrenoids, especially about its protein composition, structure, and assembly



1. What proteins form pyrenoids?
2. What keep rubisco inside pyrenoid?
3. How does it divide?

Meanwhile in bacteria…

The components of the **cyanobacterial CCMs have largely been identified**, facilitated in part by the organization of the genes encoding them into **operons**. Knowledge of these components has enabled the detailed characterization of the structure and assembly pathway of the **beta carboxysome**

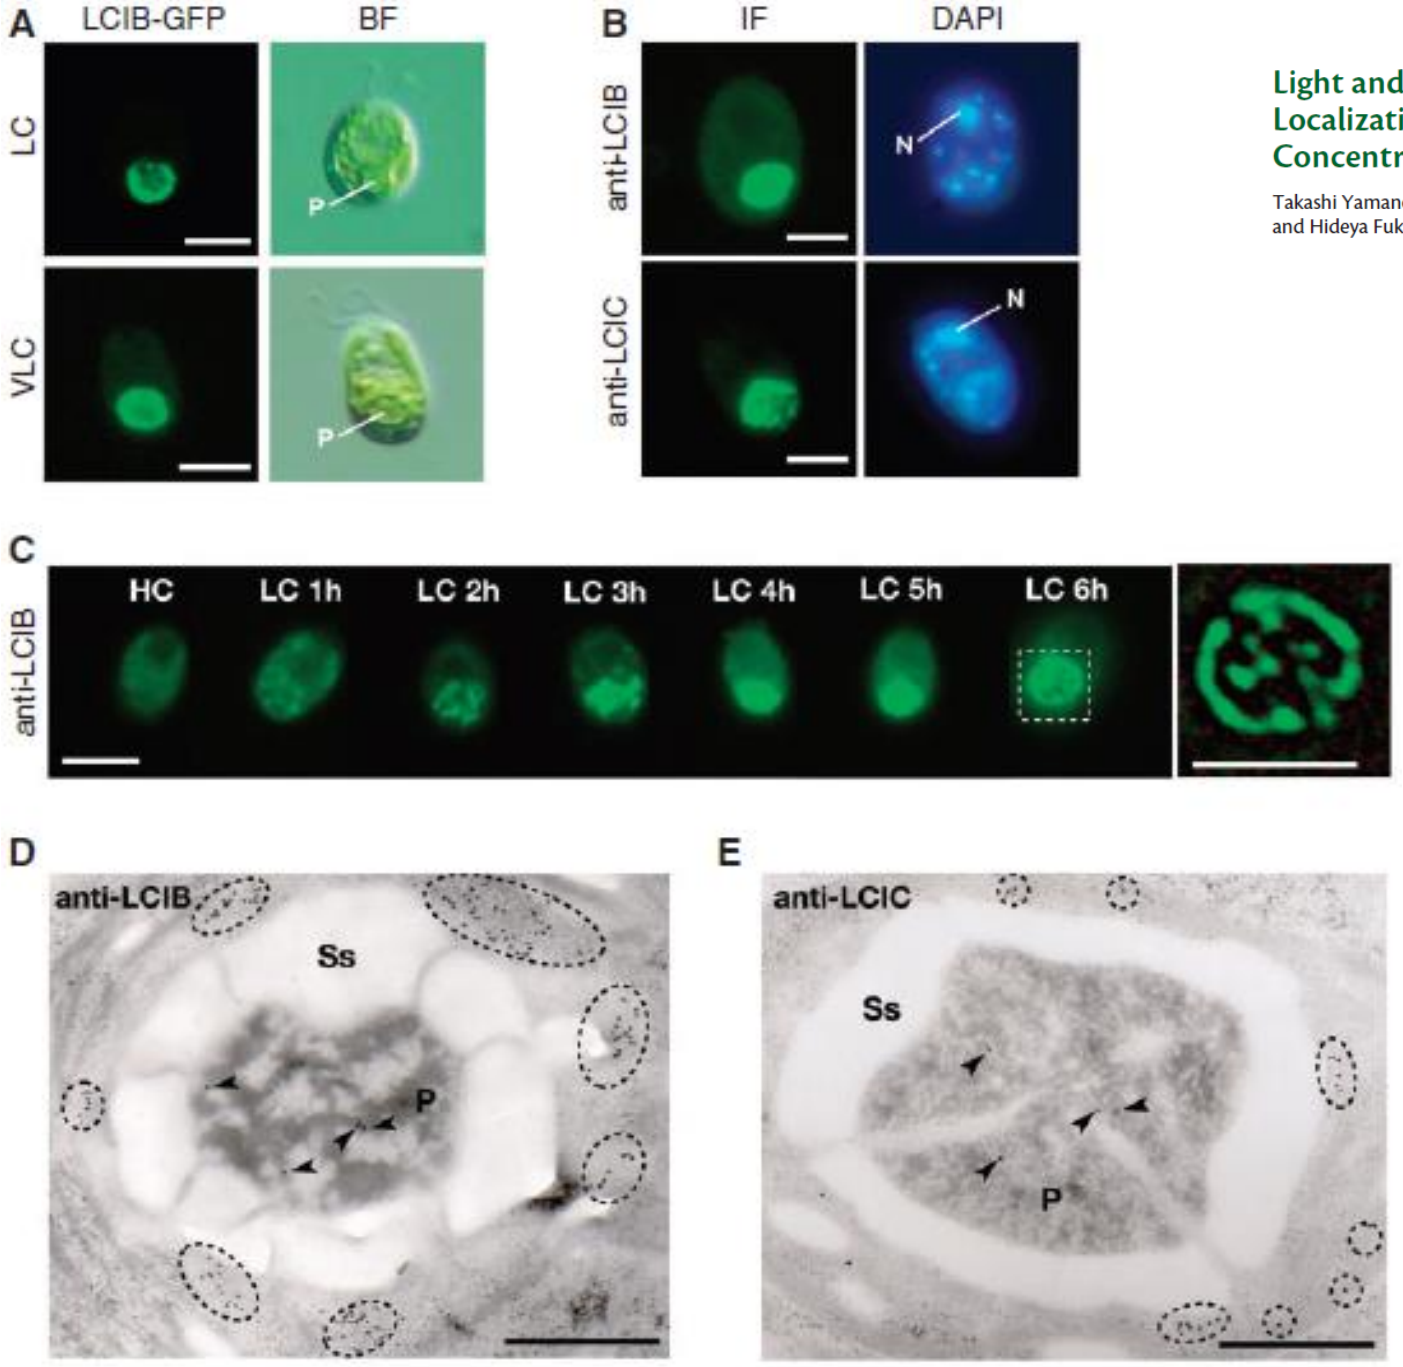
Light and Low-CO_2-Dependent LCIB–LCIC Complex Localization in the Chloroplast Supports the Carbon-Concentrating Mechanism in *Chlamydomonas reinhardtii*

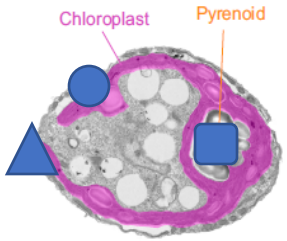
Takashi Yamano[1,4], Tomoki Tsujikawa[1], Kyoko Hatano[2], Shin-ichiro Ozawa[3,5], Yuichiro Takahashi[3] and Hideya Fukuzawa[1,*]



LCIB–LCIC complex could be related to the developing pyrenoid structure and/or formation of starch sheaths.

Some roles to trap CO_2 leaking from the pyrenoid matrix and to transfer the captured CO_2 to stromal carbonic anhydrase CAH6

626 candidate CCM targets

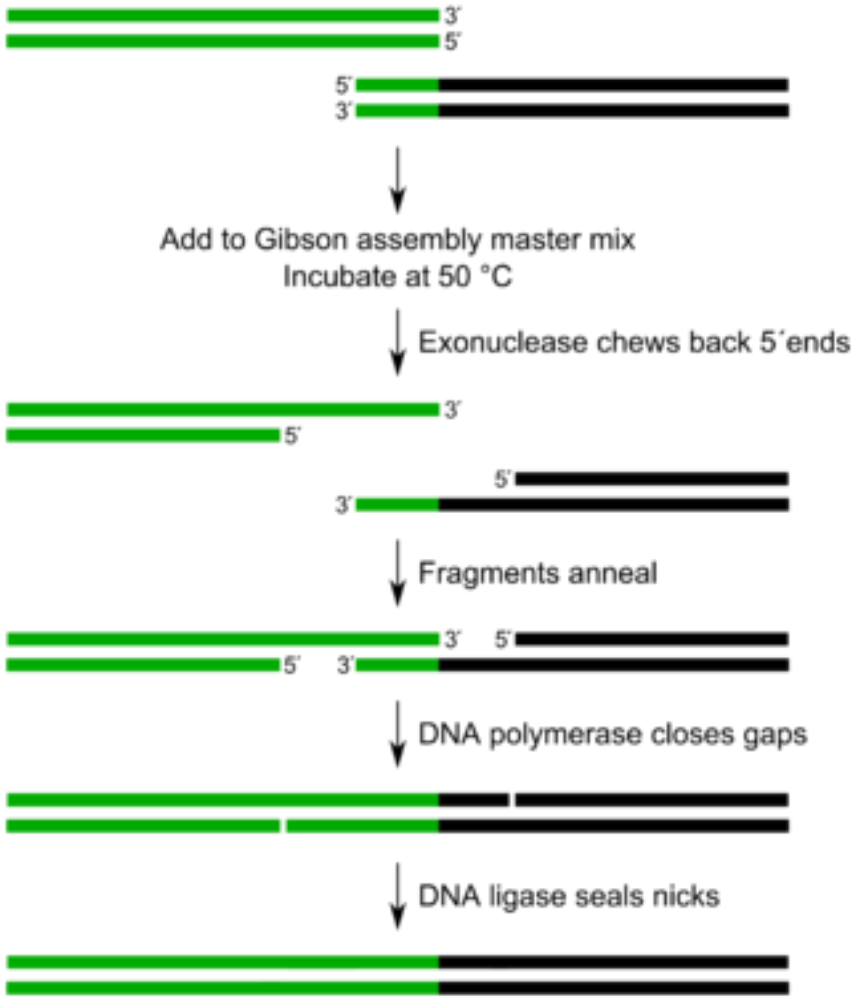


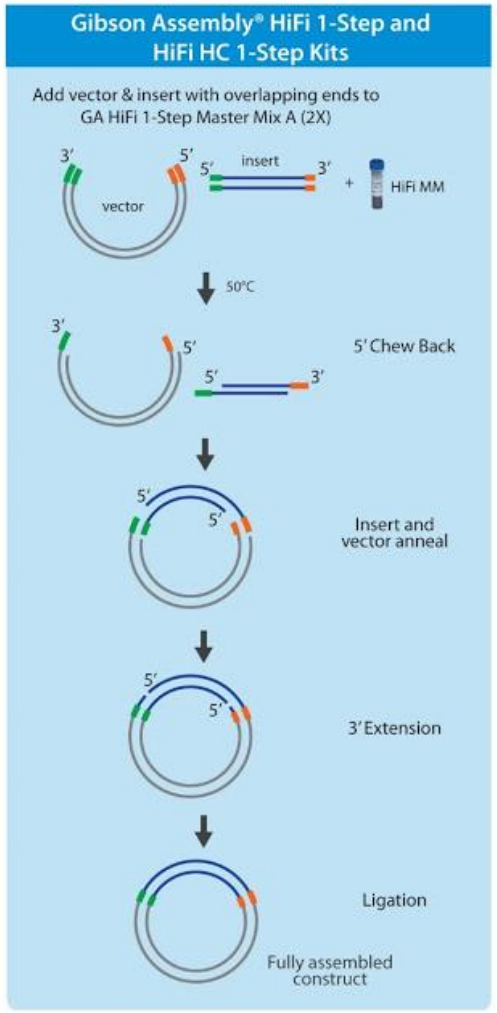
303 transformed and expressed in Chlamydomonas **(48%)**

146 were imaged and localized at subcellular level by confocal laser scanner microscopy **(23%)**

Gibson technology to clone high number of cloning sequences

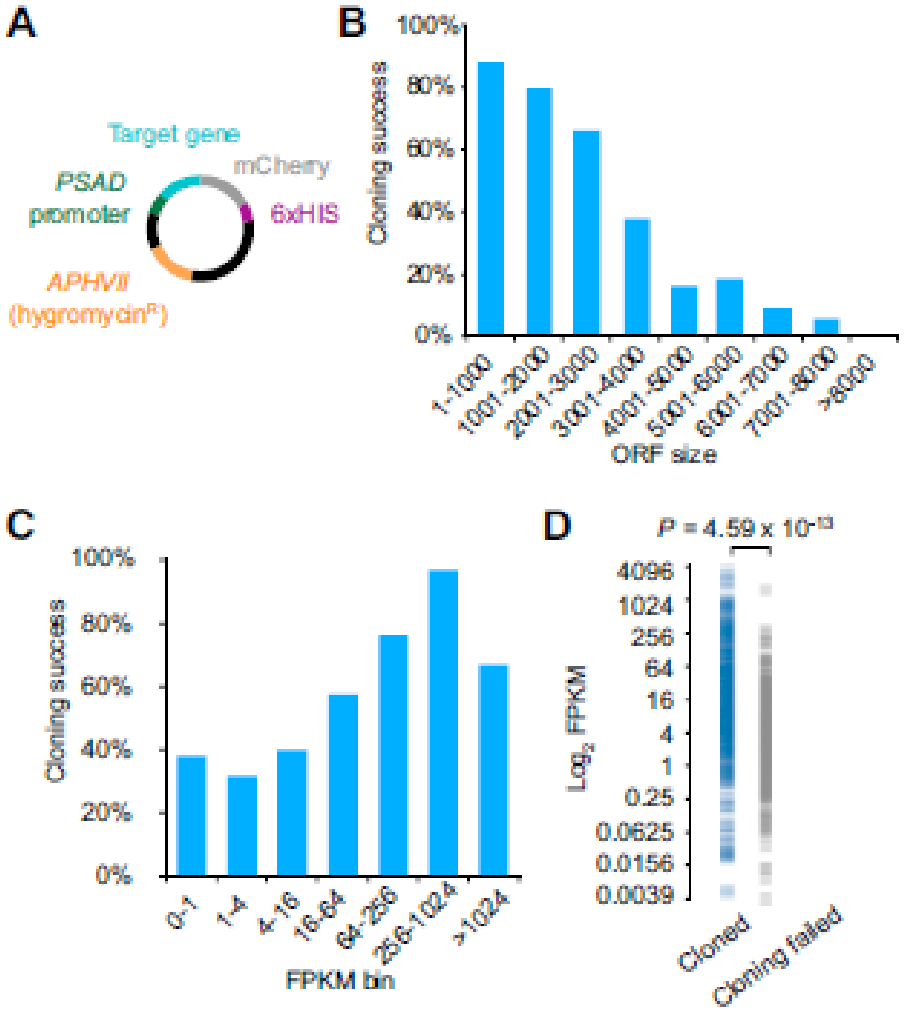
Gibson technology to clone high number of cloning sequences





Uncovering factors that may contribute to cloning and tagging success in Chlamydomonas.

They successfully cloned 303 of the 626 target genes (48%). Cloning success rate decreased with **gene size**.



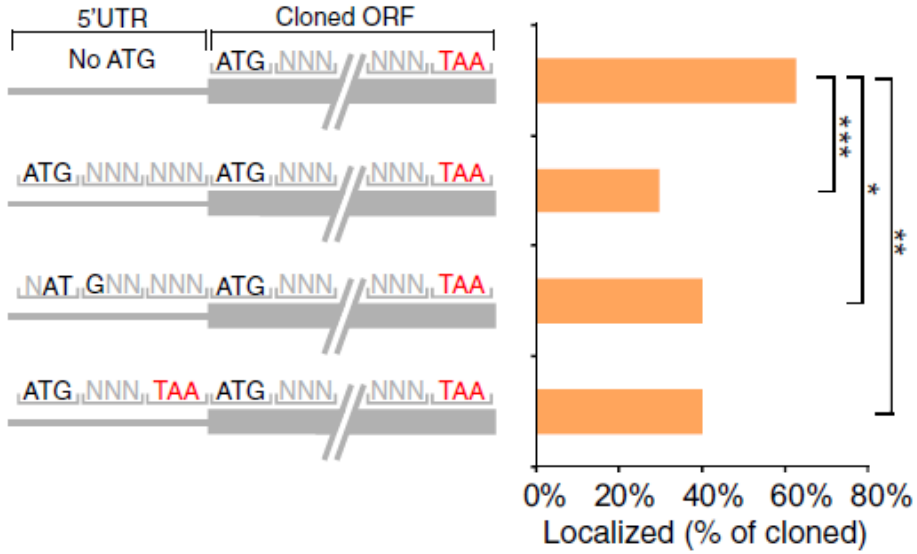
Intriguingly, cloning success was higher for genes with high expression levels ($p = 4 \times 10^{-13}$, Mann-Whitney U test), suggesting that **intrinsic properties of a gene** that influence endogenous expression may also affect PCR efficiency.

Successfully transformed and acquired protein localization data for 146 of the 303 cloned genes (49%).

The two main factors correlated with the ability to obtain localization data were:

(1) high endogenous gene expression level

(2) absence of upstream in-frame ATGs



Successfully transformed and acquired protein localization data for 146 of the 303 cloned genes (49%).

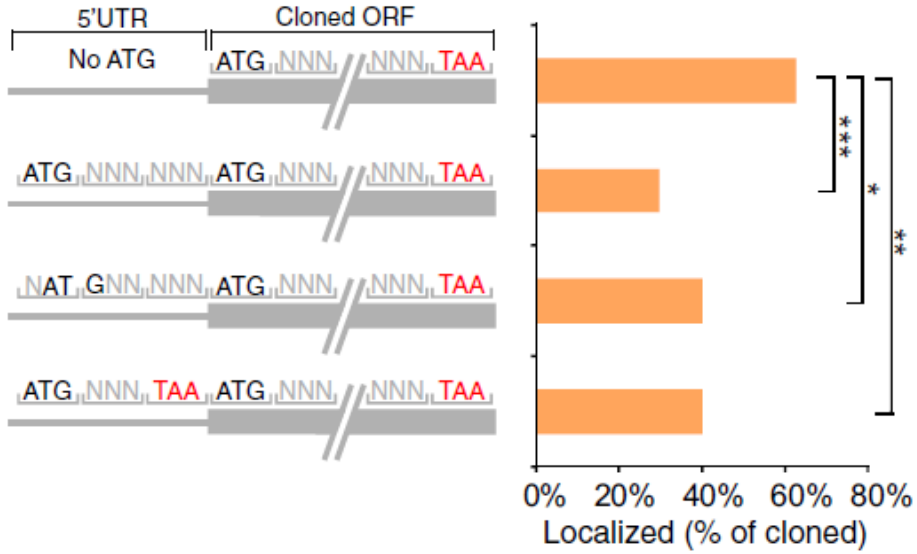
The two main factors correlated with the ability to obtain localization data were:

(1) high endogenous gene expression level

(2) absence of upstream in-frame ATGs

The failure to obtain localization data for genes with in-frame uATGs is likely due to the absence of the correct translational start site in the cloned construct.

Transcript abundance is predictive for localization success and that future protein expression studies will benefit substantially from improved annotation of Chlamydomonas translation start sites.



To aid in the classification of unknown proteins to subcellular regions, we tagged a series of conserved, well-characterized organelle and cellular structure proteins.

They employed a **decision tree to classify visually the localization of 135 additional proteins into 29 distinct subcellular regions**, representing nearly all of the known organelles and cellular structures of Chlamydomonas.

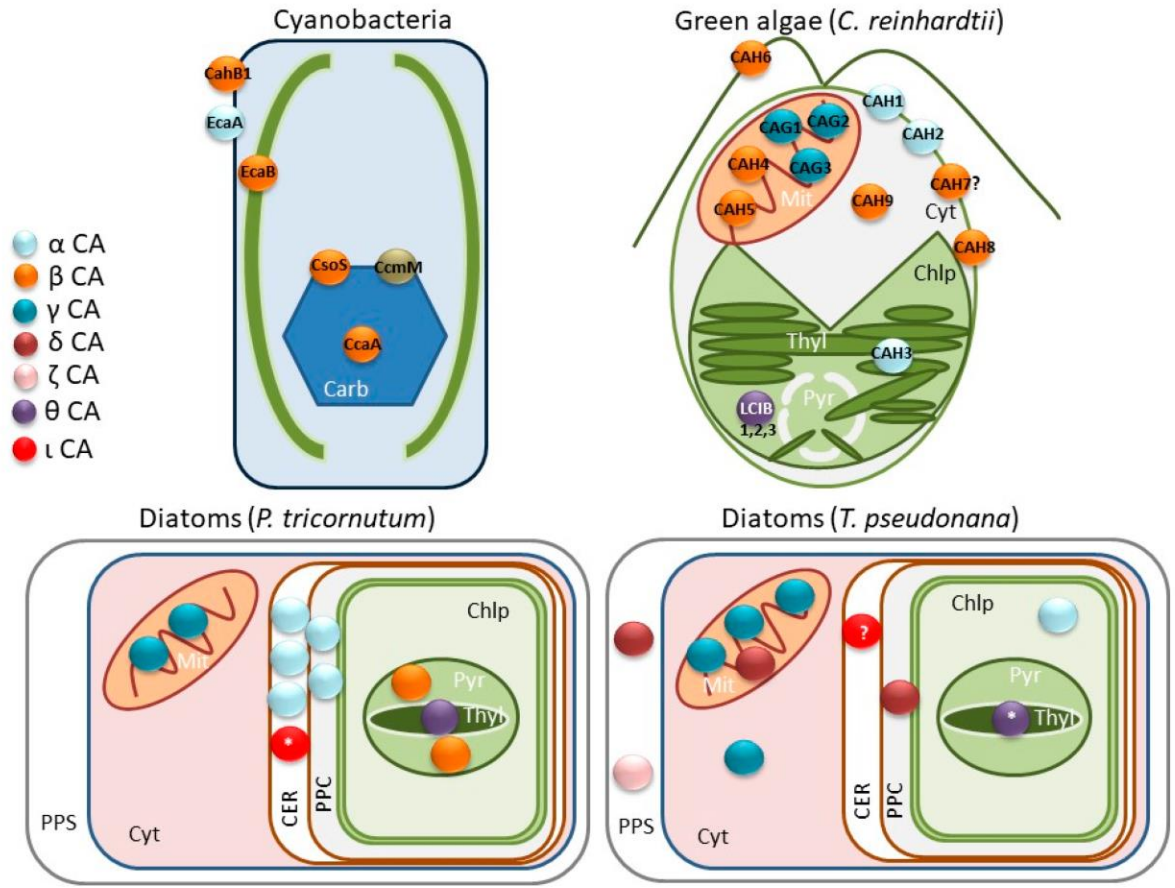
Review

Insights on the Functions and Ecophysiological Relevance of the Diverse Carbonic Anhydrases in Microalgae

Erik L. Jensen [1,†], Stephen C. Maberly [2] and Brigitte Gontero [1,*]

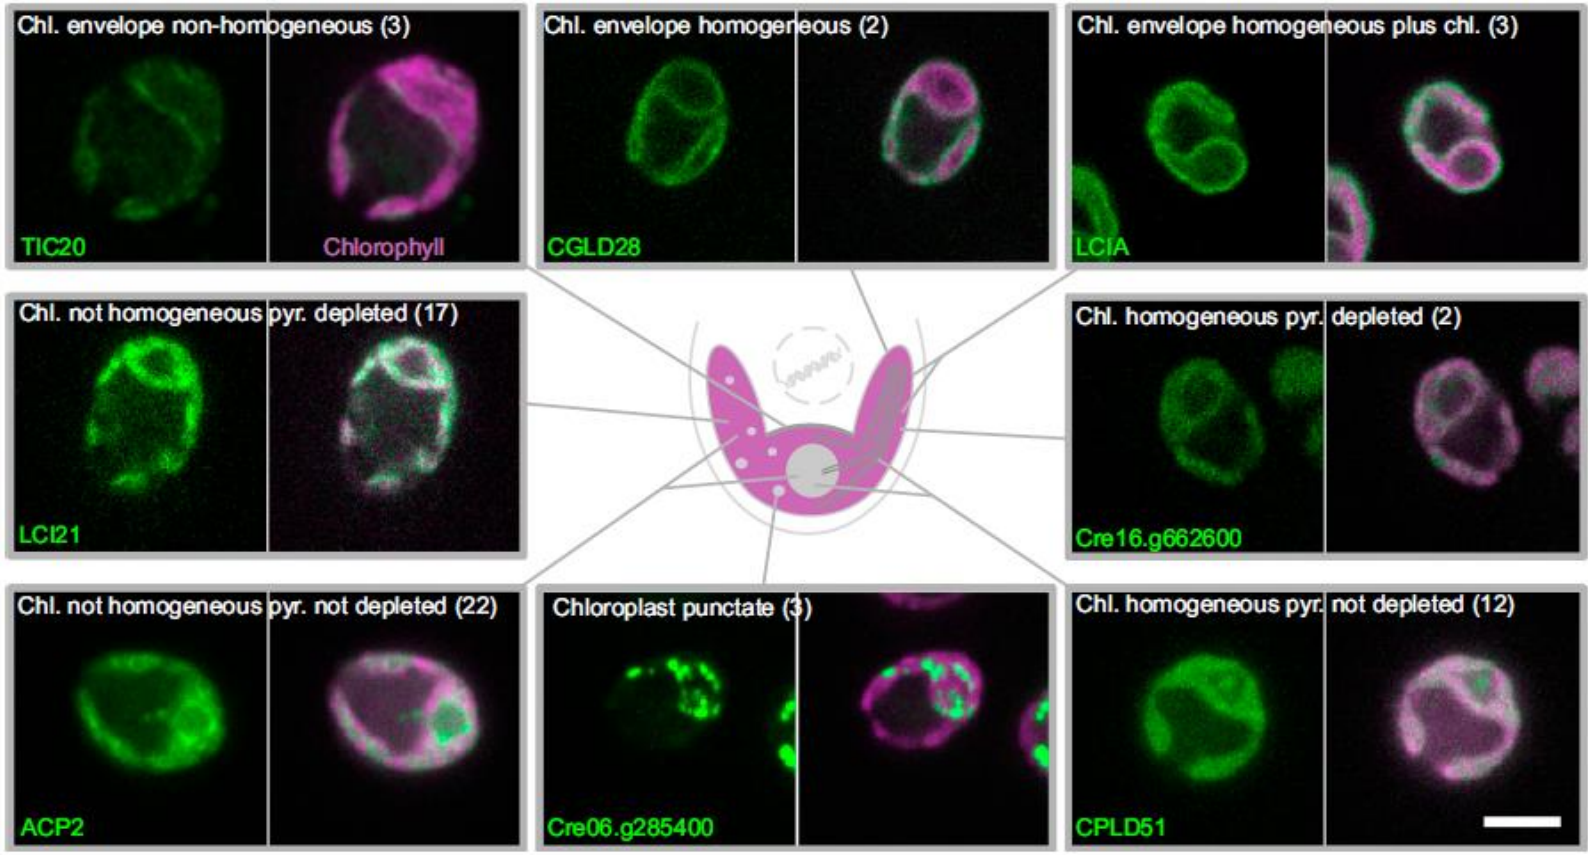


What is CAH6 doing in flagella?

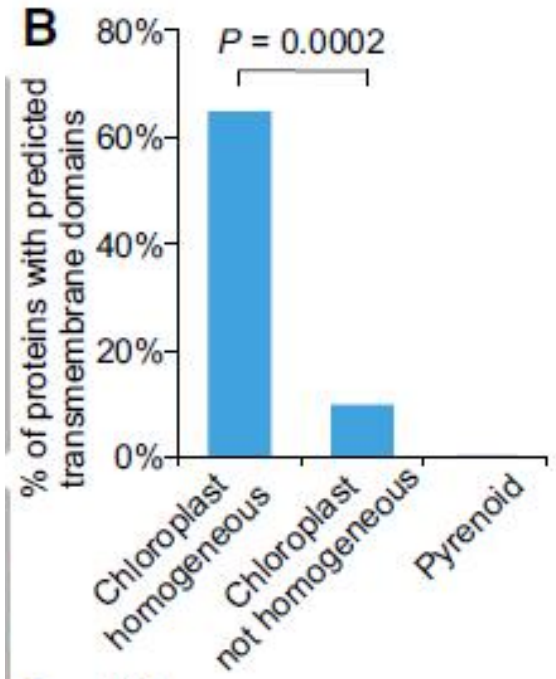
Instead of directly participating in the CCM, **CAH6 could be involved in inorganic carbon sensing**. Chlamydomonas was recently shown to **chemotax toward HCO3-** (Choi et al., 2016), and carbonic anhydrases have been previously implicated in inorganic carbon sensing (Hu et al., 2010).

Localization of sensing machinery to the flagella, which are found at the leading edge of swimming cells, could facilitate chemotaxis.

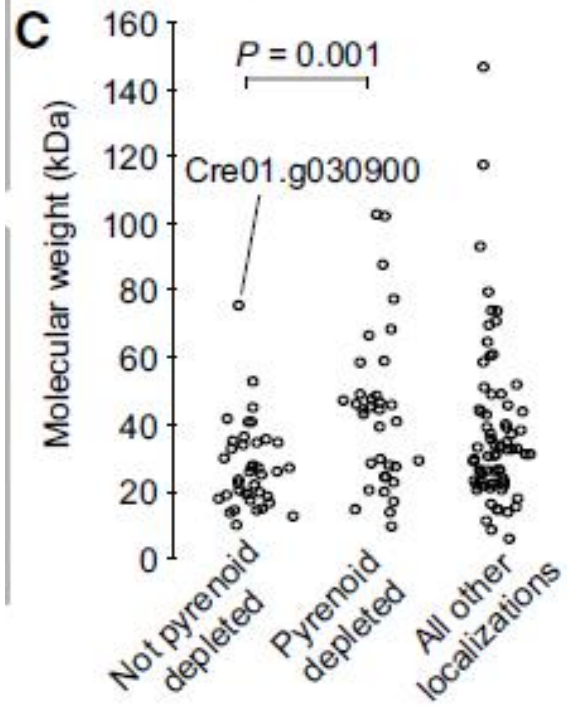
Focus on the chloroplast



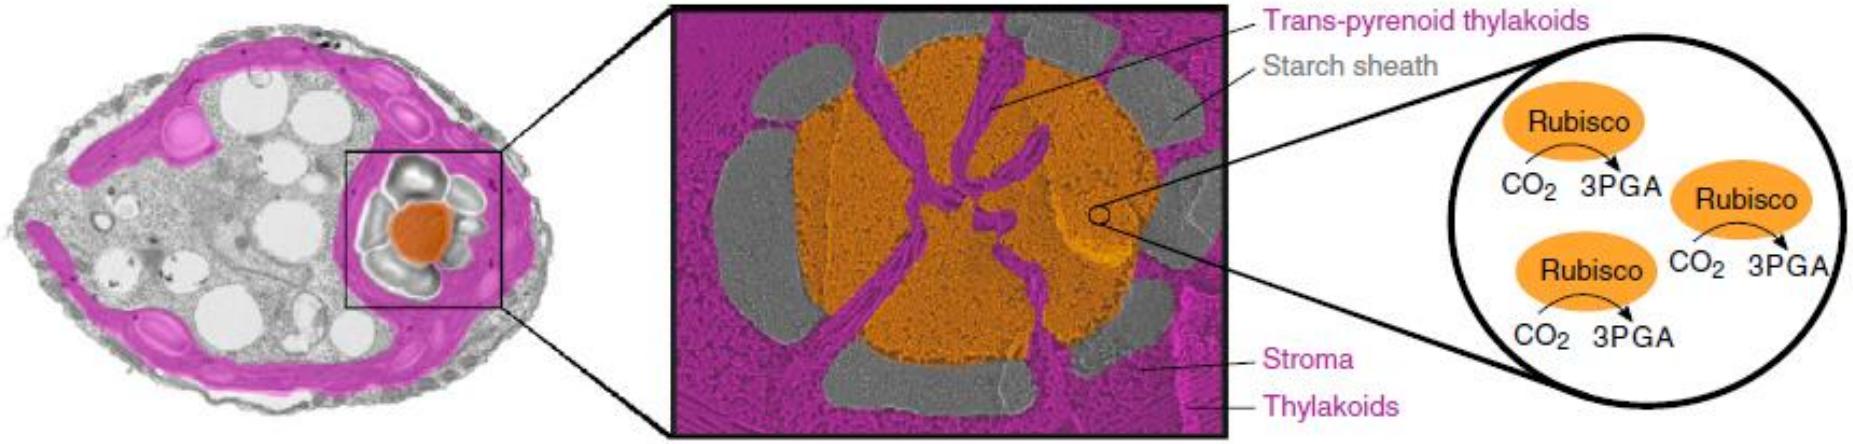
Approximately 56% (82/146) of the proteins localized to the chloroplast. They assigned these 82 proteins to 13 sub-chloroplast locations. Chloroplast envelope proteins showed three subcategories of localization: (1) envelope homogeneous, (2) envelope non-homogeneous, and (3) envelope plus chloroplast homogeneous



homogeneous chloroplast localization is a trait enriched in proteins containing transmembrane domains.
This observation suggests that **proteins with homogeneous localization are most likely thylakoid membrane-associated**.



The 39 proteins that are not pyrenoid-depleted are almost all smaller than ~50 kDa (the value of ~ 50 kDa excludes the Venus YFP region, therefore the effective molecular weight is ~ 78 kDa), suggesting that the **pyrenoid may exclude larger proteins**.



Electron microscopy-based techniques have shown that the Chlamydomonas pyrenoid contains a dense matrix of Rubisco surrounded by a starch sheath and traversed by membrane tubules formed from merged thylakoids

all food sources for life on Earth and maintains the oxygen level of the atmosphere. The human population currently stands at ~7.8 billion, and is expected to grow to ~10 billion by 2050 [1]. However, not only is the current overall **agricultural productivity** (see Glossary) not keeping pace with population growth, it is actually expected to decline in the course of this century due to climate change, especially in the southern regions of the planet [2]. For example, by 2030 Southern Africa could lose more than 30% of maize production, its main crop, and South Asia could suffer losses of more than 10% for many regional staples, such as rice, millet, and maize [3]. Climate change affects agriculture in various ways, including through changes in average and local temperatures, regional climate extremes, and droughts. In the face of these challenges, it seems unlikely that future **food security** can be ensured without increasing photosynthetic carbon fixation by genetically engineering crop plants [4–9]. Making photosynthesis more efficient would not only increase productivity but also enhance agricultural sustainability by optimizing the use of resources and minimizing the impact on the environment [10].
