Sequences with 'unusual' amino acid compositions

John C Wootton

NCBI, NIH, Bethesda, USA

Amino acid sequences of very non-random composition ('low-complexity' segments) are abundant in natural proteins. From recent statistical analyses of protein sequence databases, approximately 15% of the residues occur in segments of extreme compositional bias, and approximately 34% of proteins have at least one such interspersed segment. Sequences of many elongated non-globular domains also have non-random compositional bias, and these regions increase the proportion of residues in statistically deviant segments to approximately 25% of the database. In contrast, less than 1% of residues in known ordered crystal structures are in segments of reduced complexity. Increasingly, low-complexity segments have been implicated in crucial biological functions, shown by genetic engineering and mutagenesis experiments, variations in human disease and locations of autoimmune epitopes, but relatively little is known about their range of possible molecular structures, dynamics and interactions.

Current Opinion in Structural Biology 1994, 4:413–421

Introduction

Segments of non-random amino acid composition, or 'low-complexity' regions, are very abundant in natural protein sequences. They include sequences rich in Ala, Gly, Pro, Gln, Ser, Thr, Asn, Glu, Asp, Arg, His, Met, Lys, Ile, Leu, Val, Phe residues, or combinations of a few of these. Some segments are homopolymers or nearly so, while others are irregular mosaics of mixtures of two or a more residues, and some include short-period regular repeats. They are strikingly abundant in large multidomain polypeptides crucial in morphogenesis, embryonic development, transcriptional regulation, RNA processing, signal transduction and both intracellular and extracellular structure and integrity.

Several hundred publications from 1993 and the previous few years (too many to list individually in this review) have reported new amino acid sequences, deduced from genomic or cDNA sequences, that contain low-complexity regions or domains. Almost all authors have used terms of surprise such as 'unusual', 'unexpected', 'extraordinary' and 'remarkable', perhaps reflecting a belief that such segments are rare, which they are not, or an expectation that normal proteins should have locally complex, quasi-random compositions.

The current protein sequence and structure databases [1–4] provide rich data for determining the actual abundance and nature of low-complexity segments using appropriate mathematical definitions of complexity. The statistical improbability of several specific classes of segments has been discussed for several years by Karlin and Brendel [5–7], with emphasis on clusters of charged amino acids. Recently, more general statistical measures of compositional complexity have been applied to both amino acid and nucleotide sequences and to entire sequence databases [8•,9–11], and these form the basis for the updated surveys reviewed here. Also reviewed is recent evidence implicating some of the low-complexity segments themselves in crucial molecular interactions and biological functions of these proteins. In only a few cases are relevant physicochemical details beginning to emerge, and there are many challenges for future research at the level of molecular structure and dynamics.

Measurement of local compositional complexity

The method described below provides a measure of compositional complexity of a segment of sequence, defined as a general formal property independent of any periodic or irregular repetition of pattern [8•,9–11]. All possible segments are placed on an equal footing. For example, regions rich in generally common amino acids such as Leu, Ala and Ser are treated as no more or less surprising than segments rich in His, Met or Trp. In analyzing 'non-random' mosaics, we do not know what to expect, and in reality homopolymeric regions taken together have a very different amino acid composition from the whole sequence database [8•,11].

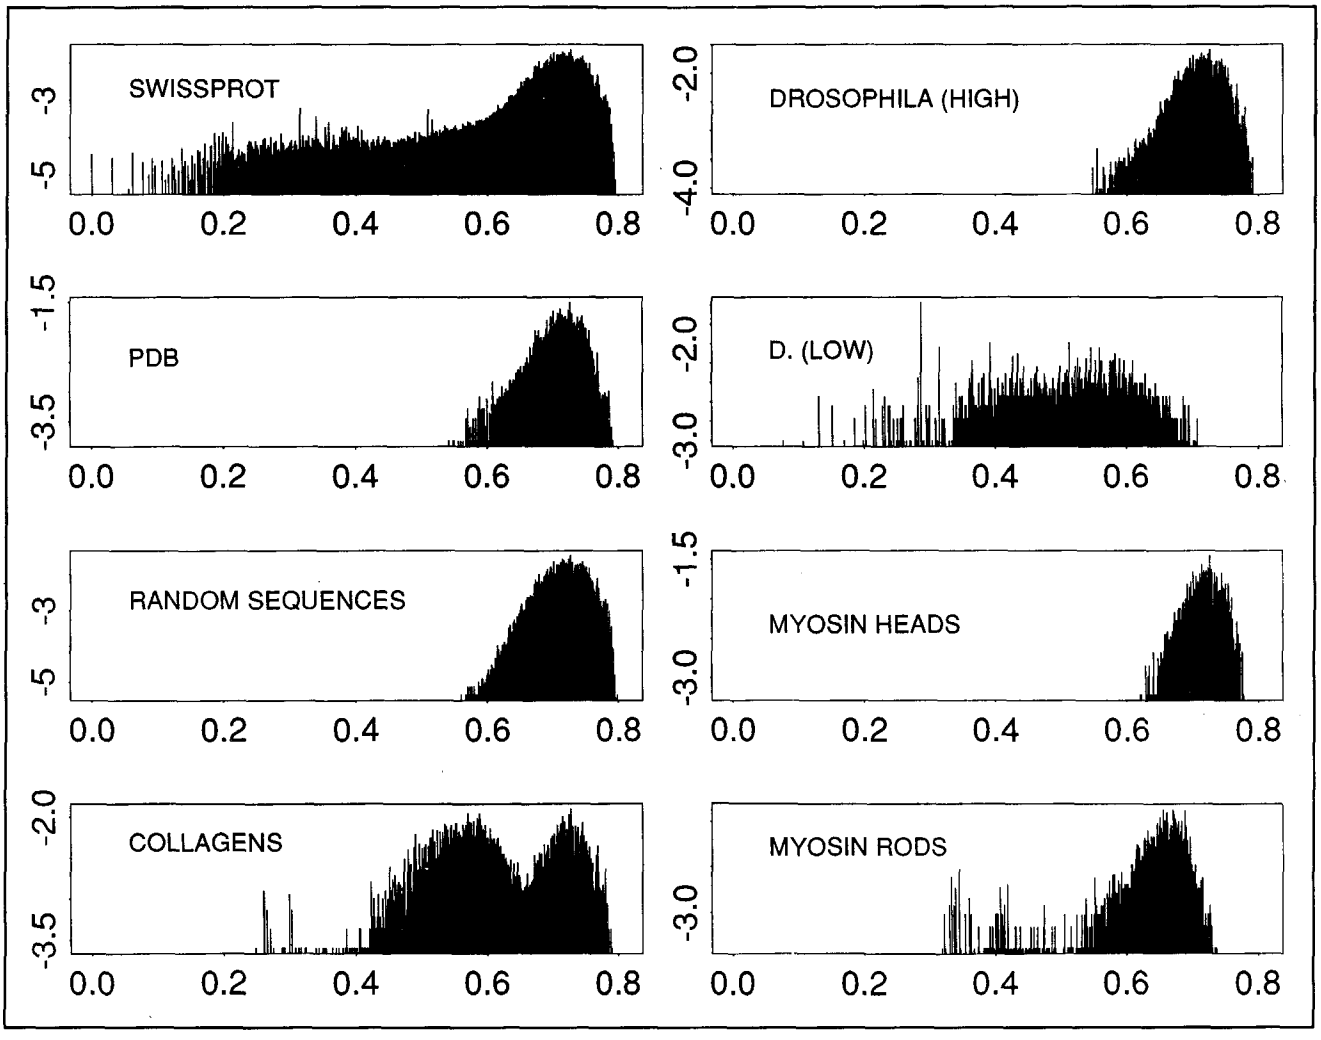

Fig. 1. Distribution of local compositional complexity in SWISS-PROT [2], PDB [4], random sequences of the same amino acid composition as SWISS-PROT, and various subsets of SWISS-PROT. The horizontal axis of each plot is Complexity K_1 (see text) calculated for all windows of length $L = 40$ moved in steps of one residue along all the sequences in each data set. The vertical axis is $\log_{20}$ (*frequency*), where *frequency* is the fraction of the total windows having each value of K_1. For $L = 40$, there are 35 251 possible complexity states. The *Drosophila* and myosin subsets of SWISS-PROT were partitioned into low-complexity and high-complexity segments using the SEG algorithm [8•] before calculation of the complexity distributions.

Compositional complexity is a function of the compositional state of a sequence segment or window. For a 12 residue peptide window, for example, the ordered vector of numbers (3,3,2,1,1,1,1,0,0,0,0,0,0,0,0,0,0,0,0,0), representing counts for the various amino acids, describes one of the 77 possible complexity states. Many possible sequences and amino acid compositions, with different residue types corresponding to the 20 numbers, share this complexity state. The local compositional complexity (K_1) of a window of length L is defined as:

$$K_1 = \frac{1}{L} \log_{20} \left(\frac{L!}{\prod_{i=1}^{20} n_i!} \right)$$

where n_i is the 20 numbers in the complexity state vector. K_1 measures the information per position needed, given the window's composition, to specify a particular residue order, regardless of which amino acids correspond to the 20 numbers in the vector and independently of the actual probabilities for appearance of the various amino acids. The probability (P_0) for the occurrence of a given complexity state, based on this assumption of uniform probabilities for the 20 amino acids, is:

$$P_0 = \frac{1}{20^L} \left(\frac{L!}{\prod_{i=1}^{20} n_i!} \right) \left(\frac{20!}{\prod_{k=0}^{L} r_k!} \right)$$

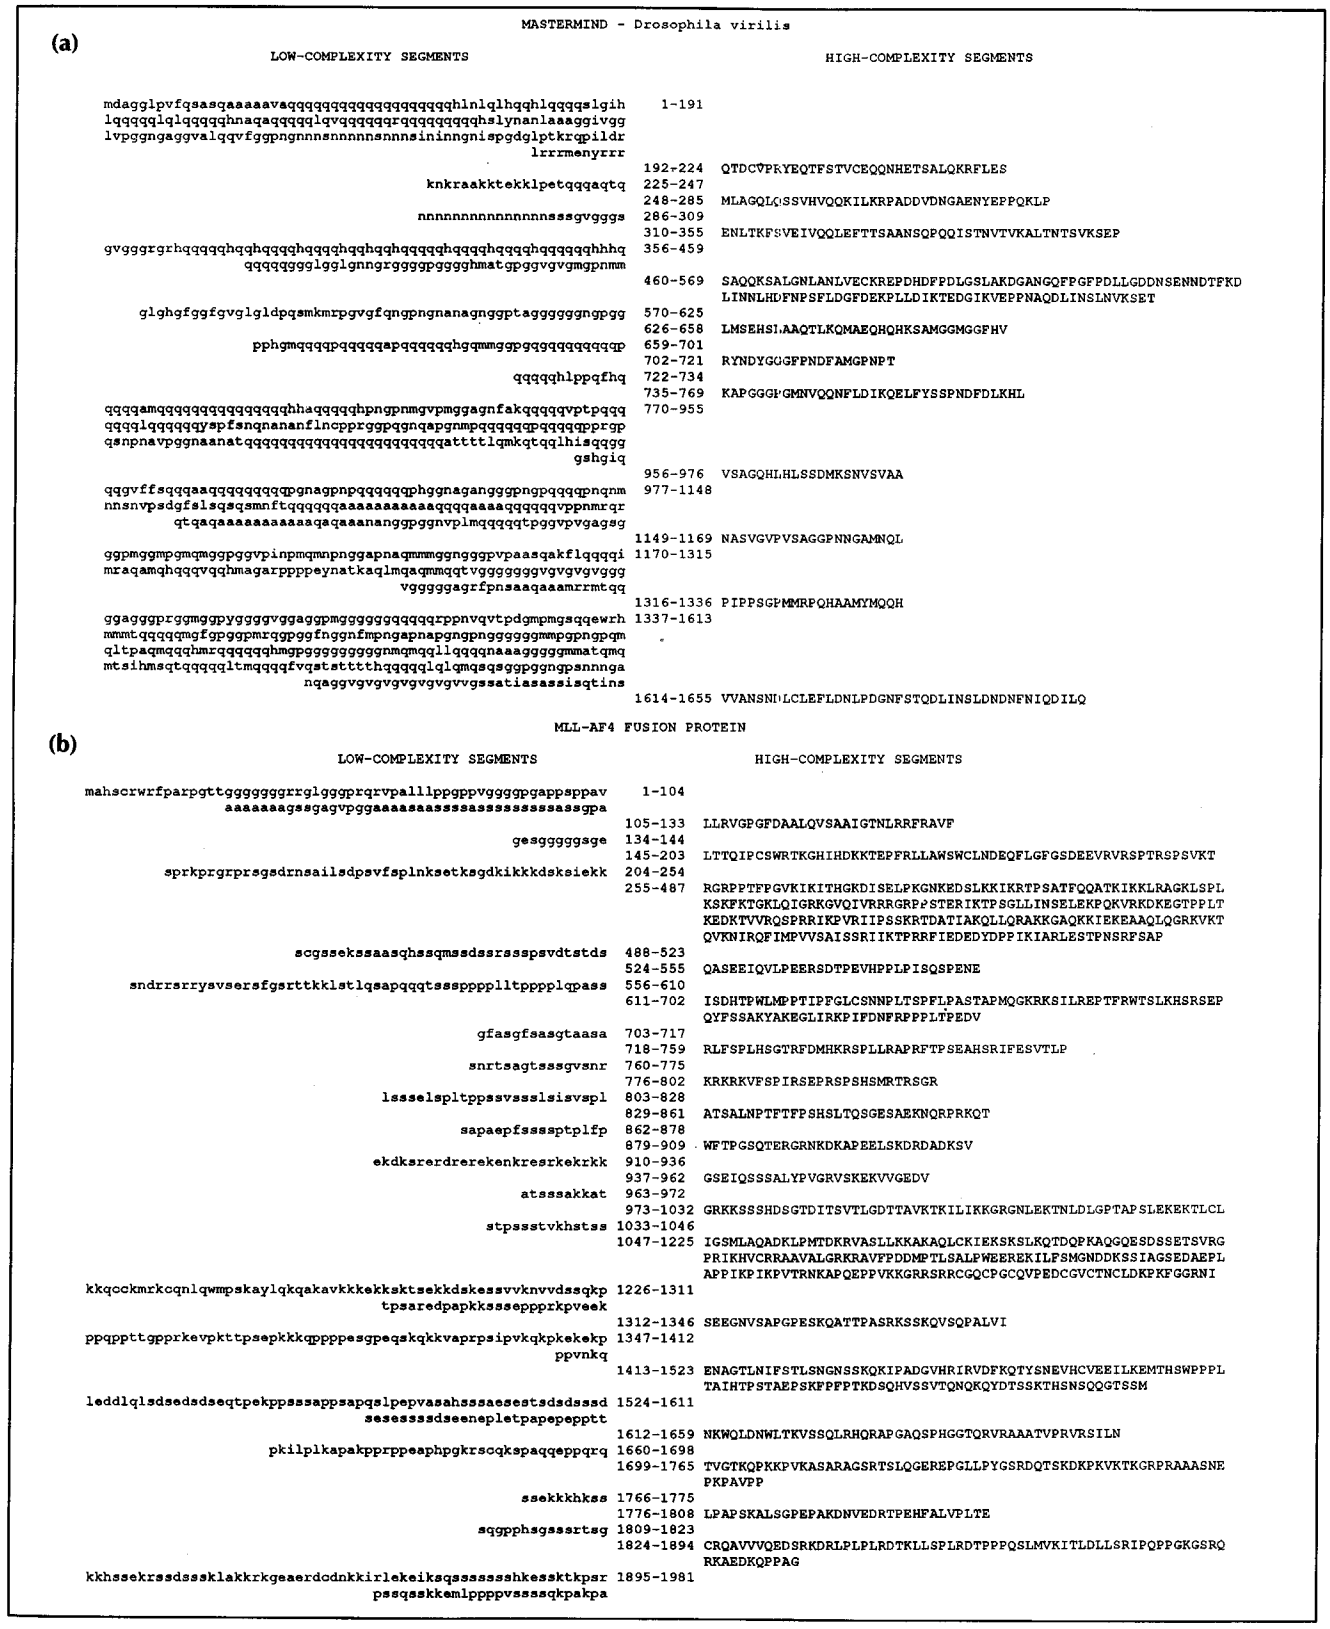

Fig. 2. Automatic segmentation of amino acid sequences into segments of low-complexity and high-complexity by the SEG algorithm [8•]. The proteins are **(a)** *Drosophila* virilis, translated product of the *mastermind* gene ([14•]; GenBank accession number M92914, locus name DROMASTM); **(b)** the MLL-AF4 translocation fusion protein in a human acute leukemia ([15•]; GenBank accession number L22179, locus name HUMMLLAF4F). All the lines of the sequence read from left to right and the order of the segments in each polypeptide runs from top to bottom, as shown by the central columns of residue numbers. The stringency of segmentation was the same for both proteins.

where r_k is the number of times that the number k occurs among n_i.

The SEG algorithm [8•,11] further develops this theory in the spirit of unbiased exploration of sequence data. The sequence or database is initially treated as a heterogeneous mixture of regions with unknown statistical properties; attempts may then be made to infer these properties. SEG first identifies all low-complexity segments in a sequence or database at a defined level of stringency, then local subsequences of minimal P_0 of any length are reported. These rigorously optimized segments correspond well with intuitive concepts of simple sequences, as illustrated below.

Masking low-complexity sequences for database searches

Low-complexity sequences create a serious problem for database search algorithms based on pair-wise sequence comparison and alignment, because they are not encompassed by the random model used by these methods to evaluate local alignment statistics [12•]. Algorithms such as SEG may be used to mask automatically the low-complexity segments in database search query sequences, replacing their residues with 'x' characters. This removes the potential confusion caused by overwhelmingly large output lists, with many spuriously high scores due to compositional bias, in which interesting similarities may be inconspicuously buried [8•,12•,13]. An important recent application of such automated masking has been in the production of precomputed sets of all amino acid sequence homologues ('neighbors') released with the NCBI databases and incorporated into the ENTREZ retrieval system [3]. Since September 1992, the entire sequence databases and all updates have been masked before searches, in order to avoid spurious matches in the neighbor lists.

The abundance of low complexity in protein sequence databases

Fig. 1 illustrates some of the recent results obtained from complexity measures on sequence databases and their subsets. Details of calculations of this type and the cleaned-up databases used are described in [8•,11]. The distribution of complexity K_1 shows a remarkable contrast between the sequence database SWISS-PROT (26 August 1993 release; [2]), the sequences in crystal structures from PDB (July 1993 release; [4]) and random sequences (generated with SWISS-PROT amino acid frequencies). Compared with random sequences, SWISS-PROT sequences display a substantial excess of low-complexity windows, amounting to approximately 25% of the residues. In contrast, the much smaller set of PDB sequences is very close to random in its distribution of complexity, less than 1% of the residues falling outside the random range. In species-specific subsets of SWISS-PROT, all groups of organisms (bacteria, protists, yeast, fungi, plants and animals) show an abundance of low-complexity segments, varying from 11% (*Escherichia coli*) through 24% (human) to 36% (*Drosophila*) of the residues [11]. Fig. 1 shows *Drosophila* results as an example.

The upper end of 'low complexity' includes some relatively well understood, long, non-globular domains of proteins, in addition to many new classes [11]. These include collagens (Fig. 1), which exhibit a bimodal distribution of local complexity corresponding to the windows from the triple-helical rod and globular domains, and coiled-coil proteins such as myosins (Fig. 1) for which the SEG algorithm may be used (with appropriate parameters) to separate cleanly the globular head sequences from the variably repeated coiled-coil sequences. Similar distributions are found with keratins, other intermediate filament proteins, proteoglycan core proteins, mucins, elastins and fibrins [11]. These results support the concept of a general correlation between non-random (reduced) compositional complexity and non-globular elongated structure. Any tendency, however slight, towards regular sequence repetition, as occurs in these helical structures, will inevitably generate relatively lower values of K_1 at sufficiently long window length.

If we discount these known non-globular, 'medium-complexity' structures, a conservative estimate still counts 15% of the residues in the sequence database as occurring in segments of strikingly low complexity [8•,11]. The dramatic meaning of 'strikingly' is illustrated by two important examples published in 1993 (Fig. 2; [14•,15•]). The SEG algorithm also shows that approximately 34% of the sequence entries in SWISS-PROT contain at least one such (relatively stringently defined) low-complexity segment; this increases to 56% if stringency is relaxed to include potential long non-globular regions of non-random low complexity [11].

Speculations that extrapolate from the current sequence and structure databases of natural proteins suggest that there may be only a limited number of 'ancient conserved regions' or alignable sequence families, corresponding to globular topological folds [16,17]. Possibly, extrapolating even further into uncertainty, globular domains that are conserved across different phyla may account for little more than half of the residues in the total set of genome-encoded protein products, with low-complexity segments, non-globular regions, and relatively non-conserved globular domains making up the rest.

Randomness, compactness and structural uniqueness

Evidently, the PDB almost exclusively contains sequences of high compositional complexity, similar

to random sequences, presumably because compact globular proteins that form relatively unique folds and highly-ordered crystals have this property (Fig. 1; [11]). Thus, the 'globular perspective' on the current database of protein sequences is to think of quasi-random, high compositional complexity as the norm, with low-complexity sequences deviating from this norm to different extents. There is a long history of the idea that globular structures resemble random sequences in local composition, although interesting subtle differences exist (Finkelstein, this issue, pp 422–428; [18,19]). This idea is now supported by these rigorous complexity measurements (Fig. 1; [4,11]) and other database analyses [20,21]. Conversely, random permutations of the sequences of globular proteins may have a high probability of forming compact folded structures [18]. Perhaps, as a general design principle for proteins and protein-like polymers, high compositional complexity is a necessary condition for the formation of a unique globular fold that has intricate, tight packing of side chains into a solvent-excluding core. Low-complexity sequences, even those with an appropriate proportion of hydrophobic side chains to favour relatively compact structures, are more likely to generate relatively extended coiled or helical structures or mobile states resembling molten globules.

Structures and dynamics

Low-complexity sequences are expected to show a wide range of deviations from structural compactness and conformational uniqueness, from helical ellipsoidal domains, through elongated rods, to mobile coils resembling synthetic homopolymers or co-polymers. Recent insights into this difficult area have come from several interesting crystal structures of proteins with well defined, elongated, helical, non-globular domains [22,23•–25•,26]. These domains show sequence repeats some of which are very subtle. The SEG algorithm can distinguish the globular and non-globular domains of these proteins on criteria of compositional complexity (JC Wootton, unpublished data). These non-globular architectures have packed, hydrophobic interiors that are protected from solvent exposure to different extents, but these contrast with typical globular proteins in being narrow and elongated, with stacked patterns of interlocked side chains. These domains are essentially intermediate between globular structures and long rods such as alpha-helical coiled-coils and collagen, in which interlocking of hydrophobic side chains occurs to a limited extent in a relatively solvent-exposed environment.

In contrast, very little is known about the structures and dynamics of the abundant low-complexity regions interspersed within the sequences of complex multidomain proteins. Many of these are hydrophilic and likely to be relatively mobile. Some may form single solvent-exposed alpha helices, as suggested by i+3 and i+4 complementary charge patterns, but most lack such patterns. Their conformational states are likely to be determined by a number of factors: torsional constraints in the polypeptide backbone; electrostatic interactions and hydrogen bonds involving solvent molecules and ions; and hydrodynamic effects. Multiple chains may interact, possibly with cross-linking in some cases, and complex processive assembly mechanisms may occur. Conformational adaptability in interactions with intracellular and extracellular molecular complexes may be crucial for cellular mechanics, dynamics and morphogenesis. This is an important area for future research.

Evolution and functions

Many DNA sequences encoding low-complexity regions of proteins evidently evolve rapidly by processes such as recombinational repeat expansion and deletion, replication slippage and a high frequency of substitution mutations. In this respect, such sequences resemble other simple DNA sequences found in non-coding sequences such as variable number tandem repeats and microsatellites. Polymorphic trinucleotide repeats implicated in several human genetic diseases [27] provide extreme examples. Some of these repeats occur in coding sequences, generating variable-length homopolymers, such as polyglutamine, whereas others are in untranslated regions.

Rapid evolution involving length changes has been clearly demonstrated recently by several interspecific comparisons of low-complexity sequences [14•,28–31], with interesting implications for studies of the mechanisms of mutational dynamics [10,27,32]. These studies emphasize the importance of questions about the range of phenotypic consequences of these mutational changes and the extent to which the observed spectrum of low-complexity sequence features is generated by mutational drive rather than selection at the protein level. Do rapid mutational changes in low-complexity segments generate important phenotypic innovation in the evolution of organisms with complex development and morphology? What is the magnitude of the genetic load imposed by this type of genome/phenotype flux?

Recently, several important interactions, functions and phenotypes have been attributed to low-complexity segments (Table 1). These include tumorigenesis, specific DNA and RNA binding, interactions in transcriptional regulation, selection of pre-mRNAs for splicing in nuclear RNP complexes, protein–protein interactions in signal transduction, control of protein folding and turnover, and specific roles in cellular and extracellular mechanics. Clearly, many low-complexity regions in multidomain proteins are not merely present in non-essential regions as a result of mutational drive, nor do they simply act as linkers.

Table 1. Interactions, functions and phenotypes recently attributed to low-complexity segments.

Protein(s)	Function	Example of low-complexity segment involved[b]
Involved in tumorigenesis or tumor suppression		
MLL[a]fusion proteins in acute lymphoblastic leukemia	Ser-Pro-rich segments fused to MLL by chromosomal translocations t(4:11) and t(11:9) involved in tumorigenesis [15•,33•]	PPSSSAPPSAPQSLPEPVASAHSSSAESESTSDSDSSSDSES ESSSSDSEENEPLETPAPEPEPP

HIV Tat and Rev proteins	Binding to TAR RNA stem-loop [42]	RKKRRQRRRPPQNS
Interactions in transcription and transcriptional regulation.		
RNA polymerase II, largest subunit	Repeats of carboxy-terminal domain variably phosphorylatedon Ser/Thr; multiple interactions in transcription postulated [43]	YSPTSPS and variants repeated 26–52 times

Conclusion

The importance and urgency of continued research on low-complexity regions is underlined by their range of important interactions and functions (Table 1), including their involvement in human molecular diseases [15•,27,33•,34] and as epitopes in autoimmune diseases [21,35]. They are, however, characteristically difficult to study at the molecular level.

They are often heterogeneously modified, for example by phosphorylation, methylation or glycosylation [36,37•]. Many are conformationally mobile and others form defined non-globular structures which may be polymorphic or cross-linked and assembled into relatively intractable complexes. Few readily form ordered crystals. Repetitive sequences are also difficult for NMR studies because of ambiguities in unique nuclear Overhauser enhancement (NOE) assignments.

In the face of these difficulties, it is helpful to have clear statistical criteria to identify low-complexity sequences and classify them by attributes such as composition, k-gram patterns and periodicity [7,8•,9–11]. There is also scope for critical and imaginative theoretical modelling studies based on principles of protein conformation and architecture, although these may depend more on relatively unfamiliar considerations of torsional and hydrodynamic constraints, solvent interactions and conformational entropy, rather than on empirical potentials of mean force derived from the database of globular structures. However, the major challenges are for ingenious combinations of experimental methods involving new genetic expression

This paper reports interesting sequence simplifications engineered into the essential RNA binding helix-loop of methionyl-tRNA synthetase. Variants with up to 17 alanine and serine residues (out of 30) retain activity and specificity.

Arginine-specific methyltransferases demonstrate strong binding and activity for Gly-Arg-rich sequences resembling those of nucleolin, fibrillarin and hnRNP core proteins. This provides a clear demonstration of a specific interaction involving low-complexity segments.

Mutagenesis experiments implicate hydrophobic residues within the glutamine-rich activation domain in a crucial specific interaction in transcription activation. The glutamine residues themselves are evidently not critical. This clarifies the distinction between glutamine richness *per se*, the molecular significance of which is still poorly understood, and the critical binding specificities.
